Brünning,[8] in March, 1905, declared that Koplik's symptom was of great value, that it was seen in no disease but measles, and that it was frequently overlooked. Brünning believed that the early detection of the spots would be of service as a prophylactic measure, but Cotter, some time before, while describing a measles epidemic at the New York Foundling Hospital, had demonstrated that this hope was hardly warranted.

Cotter[9] published an analysis of 187 cases, in 169 of which Koplik's spots were positively present, their occurrence was doubtful in 10, and they were absent in 8; he noted that they appeared from five days to twenty-four hours before the skin eruption; in two cases, however, the spots appeared after the rash, and one case presented the spots and ran a febrile course without a rash.

Merk,[10] Professor of Dermatology at Innsbruch, late last year (1905) recorded a series of cases, five in all, occurring in one family, in none of which had he found Koplik's. Merk was interested in the cases because only three exhibited a rash, two running their course without a rash, but subsequently developing urticaria.

Ballico,[11] assistant to the chair of Pediatrics at Parma, in 1905, reported that in the examination of 63 cases of measles he found the symptom with certainty only thirty-four times; he does not accept the spots as very definitely diagnostic, and points to several reports of their having been noted in cases of rubella, pertussis, varicella, and tonsillitis. Ballico also sums up the experiences of several observers in the following truly motley array of percentages: The symptom was noted by Sippel in 98 per cent. of the cases; by Averbach in 85 per cent.; by Widowitz in 86.6 per cent.; by Michellozzi in 18.7 per cent.; by Havas in 8.25 per cent.; by Aronheim, in the series mentioned before, in 6 per cent.

At the New York Foundling Hospital in the spring and summer of 1905 a small epidemic of about 60 cases, and an epidemic of about 200 cases in the spring of 1906, furnished the bulk of the material for this study. An additional opportunity for observation was afforded by an epidemic of about 85 cases in another institution for older children, ranging from five to fourteen years, during the recent summer (1906).

Frequency.—From the records of 230 of the Foundling Hospital cases in which the presence or absence of the spots was noted, they were definitely present in 217, doubtful in 2, and absent in 11. But owing to a tendency of the buccal eruption to fade early, sometimes, indeed, before the appearance of the skin eruption, and frequently before the rash has fully bloomed, it is only fair to state that in 8 of the 11 cases in which the spots were not found they were not sought until the rash had begun to fade, in one other case the rash was just at full bloom, leaving only 2 cases in which the spots were definitely absent throughout the whole course of the disease.

In the 85 cases studied in the institution for older children the symptom was found in every case, with the exception of a few that were not examined until the skin eruption had begun to fade.

The *sequence* of Koplik's symptom and the skin eruption was studied in 154 of the Foundling Hospital cases and it was noted that the Koplik spots appeared four days before the rash in 5 cases; three days before the rash in 5 cases; two days before the rash in 29 cases; one day before the rash in 70 cases; less than one day or synchronous with the rash in 42 cases; twenty-four hours after the rash in 3 cases.

In these children the very first erythema on the forehead or behind the ears was taken to be the beginning of the rash, and it will be seen that the spots on the buccal mucosa preceded the appearance of the exanthem by only twenty-four hours or less in the majority of the cases (112).

The *duration* of Koplik's symptom in 112 cases

*Paper read at a meeting of the Pediatric Section of the New York Academy of Medicine, December 13, 1906.

in which the condition of the buccal mucosa was observed during the whole course of that disease was found to be one day in 4 cases; two days in 28 cases; three days in 48 cases; four days in 28 cases; five days in 2 cases; six days in 2 cases; the majority of the cases exhibiting the symptom from two to four days.

Early Disappearance.—It was found at the same time that in 99 cases in which the spots had been noted before the appearance of the rash they had disappeared in 5 cases before there was any sign of a rash, a significant fact when we reflect that if these cases had come under observation only with the appearance of the rash they would have been classed as cases in which Koplik's symptom was absent. It was a very common occurrence to have the spots disappear before the rash had reached the maximum intensity. In 141 cases with a full-blown rash the spots had already faded in 55 cases, more than a third; disappearing three days previously in 2 cases, two days previously in 2 cases, twenty-four hours before in 13 cases, and less than twenty-four hours before in 38 cases.

Altogether there can hardly be a doubt that Koplik's symptom is a valuable and consistent early symptom of measles and a diagnostic aid of the greatest importance. As to the value of the symptom in prophylaxis, the observations at the Foundling Hospital during the last two epidemics did not tend to confirm the hopes of Brünning and others on this point.

Frequent and careful examinations of exposed children were made and cases presenting suspicious spots on the buccal mucosa were immediately removed from the nurseries but without avail, the epidemics were not checked, and it seemed certain that infected children were capable of spreading the contagion long before they presented Koplik's spots. Instances where epidemics have apparently been checked by the removal of cases presenting the spots might have their explanation in an unusual degree of resistance possessed by the children exposed.

In the course of an epidemic in an institution it would seem that greater possibilities in the way of prophylaxis are offered by the thermometer test than by any other. For instance, at the Foundling Hospital about forty-eight children in a nursery, few of whom had already had measles, were accidentally exposed to infection; the primary case when detected showed a number of Koplik's spots and a beginning rash, and was immediately removed. After a period of seven days the temperature of each child in the nursery was taken per rectum twice a day and any child showing a rise in temperature was immediately removed and isolated as a suspected case. By this plan six children were removed from the nursery from nine to twelve days after the removal of the primary case, all subsequently developed measles, and no other cases occurred in the nursery. One of the 6 cases had fever five days before the Koplik's spots and six days before the rash; two had fever thirty-six hours before the spots; two twenty-four hours before; and one less than twenty-four hours before the spots.

In all probability the febrile movement of the prodromal stage almost invariably precedes by a considerable period the appearance of Koplik's symptom, and its recognition would be of greater prophylactic value than the detection of the spots.

From these observations it would seem that:

1. Koplik's symptom is a constant, definite, early diagnostic sign of measles, of greater diagnostic value when present than even the rash. The constancy of the symptom is indicated by the fact that in 221 cases observed from the period of incubation well into convalescence it was definitely absent only twice.

2. Koplik's spots sometimes disappear before there is any sign of a skin eruption, and frequently before the rash has fully bloomed.

3. Cases seen in the earliest stages and presenting but few Koplik's spots as yet are known to have infected exposed children, and for this reason the early detection of the spots can hardly be expected to prove a prophylactic measure of any great value.

4. Koplik's symptom is usually, if not always, preceded by a febrile movement, and the thermometer would seem to be the best aid to early diagnosis when dealing with an epidemic in an institution.

THE RADICAL CURE OF TRIGEMINAL NEURALGIA BY MEANS OF PERIPHERAL OPERATIONS.*

By ALEXIS V. MOSCHCOWITZ, M.D.,

NEW YORK,

Attending Surgeon, Mount Sinai Hospital.

In an article entitled "The Surgical Treatment of Trigeminal Neuralgia," which appeared in the Medical Record, September 29, 1906, I discussed in detail the reasons for the recurrences after operative treatment, and also made suggestions as to the best methods of obviating these post-operative recurrences. At that time my arguments were based on a rather limited experience and on a careful study of the literature in regard to the pathological findings in cases of reported recurrences. Since then it has been my good fortune to operate on three cases of trigeminal neuralgia by the methods suggested in that article, which I wish to place on record.

Before describing these cases, it will perhaps not be amiss to again recall in brief the most salient points whereby I have arrived at my conclusions.

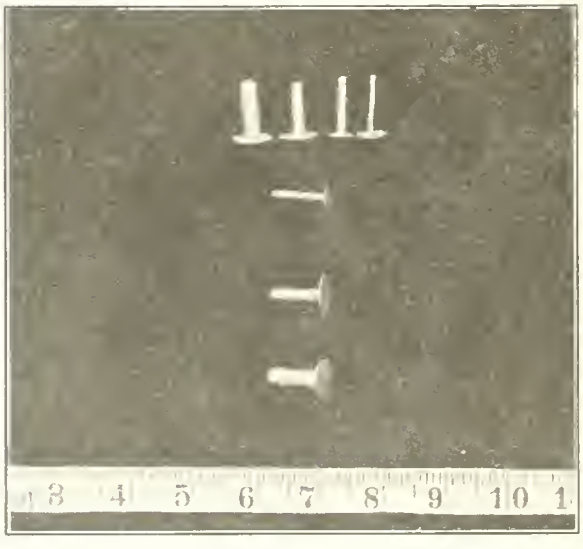
1. We know nothing of the pathological anatomy of trigeminal neuralgia. 2. All proof is lacking, that the neuralgia originates in the Gasserian ganglion. 3. All proof is lacking, that the neuralgia is of central (cerebral) origin. 4. Cures, so-called, for a longer or shorter period, have been reported, even after minor peripheral operations. 5. Relapses, after a shorter or longer period, have been reported, even after such major operations as the extirpation of the Gasserian ganglion, even in the most competent hands. 6. In the present state of our knowledge we know of no positive cure; all our treatment must be symptomatic, and we can best attain this by interrupting the conduction of the sense of pain from the affected area. 7. All recurrences have been found to be due to a regen-

*Cases presented at the Surgical Section of the Academy of Medicine, December 7, 1906.

ration and reunion of the divided nerve tissues. Every one of these points is an absolute fact, as far as our present knowledge permits, and does not require theorizing or lengthy argument; it follows, therefore, that: 8. The desideratum at present is, to prevent regeneration and reunion of the divided nerves.

Fortunately, most of the terminal endings of the trigeminal nerve make their exit from the skull through bony foramina. This naturally suggests the possibility of dividing the nerve in the canal, and preventing the reunion by permanently plugging up the foramen of exit.

After discarding various methods I have devised the following means for a permanent closure of the foramen: Messrs. Tieman & Co. prepared for me silver buttons, each consisting of a flat top not more than perhaps one-sixty-fourth of an inch in thickness, and of a diameter of about one-quarter of an inch; it is sufficiently firm to retain its shape, and yet sufficiently malleable, so that it will give, if lightly hammered upon. In its center there is annealed a silver rivet, ranging in thickness from one-thirty-second of one inch to one-eighth of one inch, and about three-eighths of one inch in length. These buttons are shown in the accompanying illustration.



The operation in appropriate cases consists in the following steps: Through an incision of suitable length, half to one inch, the foramen in question is exposed. The nerve is then carefully isolated from the accompanying vessels; a short length is drawn out of the foramen, in order to be sure that the nerve will retract sufficiently from the surface, and it is divided. The accompanying vessels are treated in a similar manner, after double ligature. A button of suitable diameter is selected and driven into the foramen, so as to fill it completely. As some foramina are not absolutely round, the overhanging flat top is now moulded to the underlying bone, so as to make the closure absolutely tight. The small cutaneous incision is closed with fine silk. If necessary the entire operation can be done in local anesthesia.

The cases I have operated in this manner are the following:

Case I.—Mrs. B. C., fifty-eight years of age, was referred to me by Dr. Wilonski, with the diagnosis of left-sided trigeminal neuralgia. The pain had existed for a number of years, and had been previously treated both by local and internal medication; most of the teeth, both of the upper and lower jaw, had been extracted. On my first examination I discovered a large polypus filling the left naris, and in order to exclude this as a possible source of the neuralgia it was removed, but without benefit. One month later she was admitted to Mount Sinai Hospital, in the service of Dr. Gerster. During her preoperative stay at the hospital we found that the attacks of neuralgia occurred at very frequent intervals, sometimes every few minutes; that the pain was very severe, and was distributed over the entire left side of the face and scalp, involving all three divisions of the fifth nerve. Pressure upon the supraorbital, infraorbital, and mental foramina was particularly painful. The left half of the tongue was also painful. Physical examination otherwise was negative; the patient was emaciated, weak, and decrepit in appearance, so as to preclude the possibility of any major operation. The patient was operated upon September 17. The mental, infraorbital, and supraorbital foramina were exposed in the order named, by small transverse incisions; the nerves divided, and the foramina plugged by means of silver buttons. When the patient reacted fully from the anesthesia, the pain had completely disappeared, and has not returned since. Primary union resulted, and patient was discharged entirely free from symptoms on September 25. The patient presents herself from time to time; thus far there is no return of the neuralgia. The buried metal causes no discomfort whatever.

Case II.—Miss A. G., sixty-seven years of age, was referred to me by Dr. H. S. Hart of Cambridge, N. Y. The neuralgic pains date back some six years, and for a long time were localized to the left cheek; gradually they extended upon the forehead and scalp; as far as could be ascertained the third division was not involved. At present the attacks come on at very frequent intervals; the slightest touch of the face or scalp being sufficient to bring on an attack. All the teeth had been extracted. I operated November 22. After exposing the left infraorbital foramen, and after division of the nerve, I plugged up the foramen with a silver button. I then exposed the supraorbital nerve, but finding only a notch instead of a foramen, had to content myself with an evulsion of the nerve. After the operation, the patient was free from pain, excepting in a very small area upon the cheek, probably supplied by the malar nerve. Primary union resulted and patient was discharged December 1. On account of an absence of the supraorbital foramen, this case cannot be considered as cured, not even tentatively. It is, however, not impossible, in view of the fact, that the second division was primarily and mainly involved, that the neuralgia in the frontal region will cease entirely, after the iritation from the second division has been excluded.

My third case, though chronologically the first one, was not operated upon with the silver buttons; it should, however, be mentioned in the same class, because the underlying principle is the same.

Case III.—H. F., forty-six years of age, was admitted to the hospital in the service of Dr. Gerster September 26, 1904. He gave a history of neuralgia, involving the left inferior dental nerve, extending over a period of several years. All of the teeth had been extracted in vain efforts to modify the attacks. He was operated upon September 29 in the following manner: Through an incision about one inch in length, extending from the agle of the jaw forward, along the inferior border, the attachment of the masseter was exposed, especial care being taken to avoid any injury of the branches of the facial nerve. The masseter and underlying perios-

teum were peeled up from the bone and retracted; a groove was now chiseled into the outer surface of the ascending ramus of the jaw, exposing the nerve in its canal; about one inch was then resected, and the wound closed without drainage. Primary union resulted, and patient was discharged October 16, relieved of his symptoms. The unusual length of stay at the hospital was due to the fact that at the same time he was operated for a right inguinal hernia. The patient was entirely free from symptoms for nine months, when the neuralgic pains returned in their original severity. He was readmitted in July, 1905. The preliminary steps of the old operation were repeated; when the groove in the ascending ramus of the lower jaw was exposed, a regenerated nerve, of apparently normal appearance and size was found; about one and one-half inches of it were again resected. Just before closing the wound, the idea occurred to me, that just as the patient was not cured by the first operation, the second one would also be ineffectual, unless something were done to prevent regeneration and reunion. Horsley's wax occurred to me at first, but I discarded it, because I feared that it would be absorbed too quickly. I thought of silver foil as a suitable material, and therefore packed the cavity full of this material. Primary union resulted, and patient was discharged two weeks later. Again his stay at the hospital was protracted by a radical operation for inguinal hernia, this time on the left side. The patient was again free from all symptoms for about nine months, when the pain returned, though in a considerably diminished degree; gradually the pain became severer, particularly at night. He was readmitted July 10, 1906. The patient was prepared for and willingly assented to an intracraneal operation, but finally a peripheral operation was again decided upon. A skiagraph at this time failed to show the presence of the silver. Operation July 19. The preliminary steps were the same as in the two previous operations. When the groove in the ascending ramus of the lower jaw was exposed, some silver foil was found in it, but evidently insufficient to give a shadow on the skiagraph, and insufficient to prevent regeneration and reunion; it was intimately incorporated with the cicatrical tissue filling the canal. It was again extirpated, and the groove firmly plugged with silverfoil, taking particular care to exert firm pressure into each angle, where presumably the ends of the nerve were. Primary union resulted, and patient was discharged July 25, free from all pain.

He presents himself from time to time; thus far there is no recurrence. He still complains of a paresthesia in the region supplied by the lingual nerve, but only in a very slight degree.

I do not present these cases as cured cases of trigeminal neuralgia; the period of observation is altogether too short to admit this deduction. It can be safely argued, however, that theoretically, at all events, there is no reason whatsoever why there should be a recurrence of the neuralgia.

Laryngeal Tuberculosis.—The local application of formalin is very highly spoken of by Lockard, who states that the remedy possesses the following advantages: It surpasses all other bactericides in solutions of a strength which can be tolerated. In tuberculous ulcers it is fully the equal of, and probably superior to, lactic acid. Its effect upon vegetations is prompt and pronounced. It possesses some anesthetic properties. It is the only remedy of the curative class that can with safety be placed in the patient's hand, thus maintaining a continuous cleansing, germicidal, and stimulating action.—*The Laryngoscope.*

PNEUMONIA IN CHILDREN: ITS SUCCESSFUL MANAGEMENT BY HYDRIATRIC MEASURES.

WITH AN ILLUSTRATIVE CASE.

By W. PARKER WORSTER, A.M., M.D.,

NEW YORK.

INSPECTOR ON ELECTROTHERAPEUTICS NEW YORK POST GRADUATE MEDICAL SCHOOL AND HOSPITAL

It is most notable that pneumonia yields with promptitude to treatment intelligently applied at an early stage of the attack. Or if the physician is not called until absolutely too late, he can readily save the patient by proper means of management; but his best efforts will be futile most certainly if he starts out with the false idea that he has to cope with a case of lung disease. Wherever, whenever, and by whom the doctrine is adopted that pneumonia is not an inflammatory process; that pneumonia is not a lung disease, any more than typhoid fever is a bowel disease, but that it is an infectious disease whose chief manifestation is in the lung,

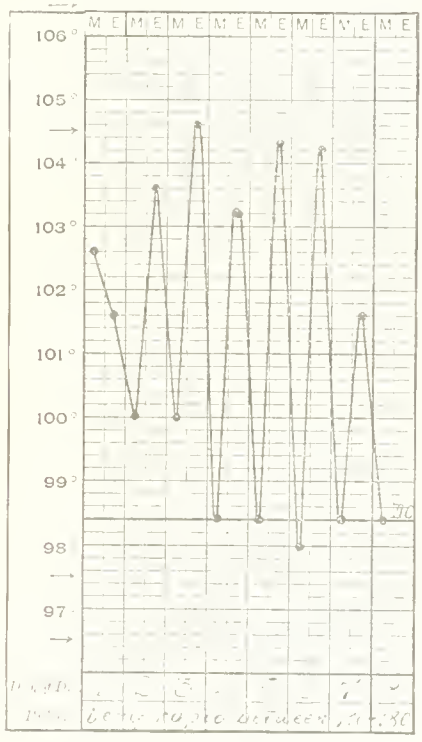


Chart of Case of Pneumonia.

dependent upon a toxemia evolved in an infection process, then the disease will cease to be treated, and the physician is prepared for the more effective management of the patient suffering from it, with the result of promoting rapid recovery and saving life. That effective management is by means of water judiciously and properly applied. It is to be regretted that there are some physicians who, emulating the fireman who quenches a fire by drowning it, think they should do the same thing in pneumonia, by pouring at the spot where the symptom seems most troublesome sledge-hammer blows of allopathic medicine, or if their school forbids that, they must anoint that spot homœopathically; either method adds fuel to the fire, and the patient dies of heart-failure. This heart feebleness arises from a paralysis of the vasomotor nerve centers, and not of the heart itself, by reason of which the capillary blood-vessels lose their elasticity and normal tone, which are essential to a properly acting vasomotor

system; the poor heart which is laboring to compensate for that loss of elasticity becomes worn out, resembling the driving wheels of the locomotive which have lost their resistance by slippery tracks, and fly around ineffectually, racking the machinery and destroying its usefulness.

Hydrotherapy counteracts collapse of the vascular walls, consequently there is no such thing as heart failure; the pulse has always gained in tension after each treatment, and no patient is too weak to bear hydrotherapy properly administered, varying it according to his condition. Nature has provided its own simple and effective remedy for pneumonia—water. Water will promptly and effectively execute its functions whenever proper, just as reflex action will promptly respond to any proper call. The toxic agent circulating in the blood in pneumonia (the diplococcus) produces a toxemia, and that toxemia spends its full force upon the nerve centers which govern the functions, thus impairing the organs dependent upon them. The object of treatment is to bridge over the danger which would arise from the failure of these functions by enhancing the patient's vital powers until the life period of the diplococcus is terminated, which is about seven days. The cold bath comes to the rescue, because cold applied to the peripheral nerve terminals of the skin produces a shock to them, and a stimulus to the sensory fibers of the skin which is conveyed to the central nervous system, which in turn sends out a reflex stimulus to the nerve centers which govern respiration, circulation, digestion, tissue building, and excretion, the five life-saving functions upon whose capacity the patient depends to withstand the toxic agents circulating in the blood. The mere lowering of the temperature is a secondary consideration, but the temperature is reduced, respiration deepened, cardiac action improved, and pulse slowed and rendered less dicrotic.

In the early stages of pneumonia in children we give the full bath, beginning when the temperature reaches 102.5° with a bath at 95° every four hours, reducing the temperature of each bath two degrees until it reaches 80°, but not going below 80°, with due regard to the effect produced. With the bathing there should be plenty of good, hard thermic friction, which is the *sine qua non* in all cold baths.

If dyspnea, somnolence, stupor, and delirium should occur, a little different method is used. The child is held in water enough to cover its hips at 100° for five minutes; after which several basins of water, having been prepared and in readiness at 70°, are held high up (the operator standing preferably upon a chair so as to get as much weight to the water as possible) are poured upon its shoulders. This can be repeated every two hours if necessary, but it is seldom necessary, for the effect is magical; the patient is aroused to consciousness, the eye brightens, inspiration is deepened, and the nervous system is refreshed as by no other remedial agent. This procedure is called an affusion, and should be used when any head symptoms make their appearance. The following case illustrates exactly how a child can be successfully managed when affected with pneumonia. Hydrotheraphy furnishes always the safest and most reliable antithermic results. Each bath generally reduces the temperature two or three degrees, and through the temperature, of course, rises again, it is generally not so high, although it may exceptionally be somewhat higher than it was before. But, whatever the immediate effect may be, the baths are repeated until the temperature is finally reduced to normal, and remains there in the morning.

On the morning of November 26, 1906, at 4 o'clock, I was summoned to see C.— S.—, aged seventeen months. I found her temperature only 101.6°, with jactitation and dyspnea. The mother told me that the day before it had some popcorn in its mouth, and while it lay on its back on her lap, by some sudden movement it had choked and began to strangle. She held it up by the feet and slapped its back violently for some minutes, head downwards. I did nothing at that visit, but ordered a teaspoonful of castor oil. At 8 A.M. I called again, and found the child with all the symptoms of croupous pneumonia, with a temperature of 102.8°, and I settled right down to the treatment of the child. A bath at 95° was given for ten minutes, with good, hard thermic friction. Also at 12 M., 4, 8, and 11 P.M., reducing the temperature of the water 2° each bath. That ended the first day.

November 27, baths at 2:30 and 9 A.M.; 12:40, 4, and 7:15 P.M.; the last three baths at 80°; no bath all night. Slept well.

November 28, baths at 12:30, 5 and 8:30 P.M., at 80°. Slept well all night. Coughed a good deal, and painful.

November 29, baths at 2 and 9 P.M. at 80°. Slept all night. Ordered compresses at 60°.

November 30, 7 P.M., the temperature having risen to 103.2°, I gave a bath at 80°. Slept all night, coughed a good deal.

December 1. Bath at 4:30 P.M. at 80°. Temperature 104.6°. 6:30 P.M. feet cold, delirium slight, lies on its mother's lap face downwards, arms extended down over the head; insomnolence and stupor. Gave an affusion at 7 P.M. of five panfuls of water at 65°. At 9 P.M. it was sitting up in bed playing with its dolls. Ordered abdominal compresses at 60°. She slept well all night.

December 2. 9 A.M. temperature normal; child sitting up in bed playing with its sister and toys. 8 P.M. temperature 101°. Ordered compresses at 60°. Slept all night; no compresses after 11 P.M.

December 3. 8 A.M., temperature normal, and child sitting up at breakfast table; she made a beautiful recovery.

Any watchful physician can obtain the same results, and every case of a child with pneumonia can be managed successfully by the same means. This child took in all seventeen baths, and one affusion at 65°, and compresses at 60°. No medicine of any kind was given except several small doses of castor oil, more as a placebo to the parents than for any other reason. The diet, of course, was of milk administered with precision in the proper quantity every two hours.

If the temperature chart is followed, it will be readily seen how the cold bath knocks the temperature down 4½° in twelve hours, with no depressing effect at all, such as always follows the use of coal tar antipyretics, but, on the contrary, showing a clear gain in favor of the patient. Just as the physician varies the dose of strychnine or any other medicinal agent to suit the indications of his case, so may the dose of water as regards variation of temperature, duration, pressure, and method, be varied to suit the reaction, age, and vital powers of the patient.

Hydrotherapy is a power for good in infectious diseases, before which all other remedies must stand aside, and the physician who follows out the above line of action need never fear for the final result, for the reason that he is giving his little patient the very best if not indeed the only chance for its life.

THE PURE-MILK PROBLEM.

It is a hopeful sign that the milk supply of New York city is being made the subject of frequent discussion at public meetings and in the daily press. There is a general agreement that there is danger in the milk furnished to the city, but opinions differ widely as to the best means of overcoming this danger. The newspapers call for pasteurization of all the milk consumed, while the Health Commissioner is quoted as opposed to municipal pasteurization and as favoring a system of inspection of the sources of the milk supply.

The milk which is brought to Manhattan every day comes from some 30,000 farms scattered through several States, some of these farms being 400 miles distant from the city. The milk reaches the consumer from fourteen to forty hours after it has been drawn from the cow. Some of these places are regular dairies, with large herds of cattle, others are small farms, with from one to half a dozen cows. A few of these dairies are owned by wealthy men and are in the nature of fads, their proprietors caring more for the scientific keep of their cows and the absolute purity of the milk they produce than they do for the profits of their venture. Yet in order to maintain some sort of relation between the debit and credit columns of the ledger it is necessary to charge a price for the products of those dairies which is prohibitive to all but the rich. The milk from these model dairies is as unobtainable by the poor as diamonds. The same is true of the milk from the commercial dairies which is certified by the Milk Commission of the County Medical Society. Twelve cents a quart, which is the price of certified milk, puts it beyond the reach of the poor, even if there were enough of it to supply them at any price. There are 1,600,000 quarts of milk consumed in New York City every day, and of this the total amount of certified milk is only about 10,000 quarts—literally a mere drop in the bucket. The work of the Milk Commission is most commendable as insuring milk of good quality to those who can afford to pay for it, but it suggests no solution of the problem of a pure milk supply for the masses. The minute supervision of a portion of the milk supplied by a few of the larger and better class of dairies is impossible of extension to the thousands of few-cow farms supplying the city. At present the Health Department has a force of fourteen inspectors and the Commissioner has asked for an appropriation to enable him to increase this force to about one hundred. If he gets his hundred inspectors, each one will have to look after 300 farms, and if he is able to inspect five every day in the week he will call at each place once in two months; if he rests one day in the week and takes a two weeks' vacation in the year, his visits will be ten weeks apart, or five in the year. The hope that such angel visits will keep the milk free from tubercle or typhoid bacilli, or even from cow dung, is, we fear, utopian. The inspector, in his hurried call, may be able to suspect the evidence of advanced tuberculosis in a cow or in a milker, and he may by good detective work learn that there is a case of typhoid fever in the farmer's family; he may even form a judgment as to the observance or non-observance of the ordinary rules of cleanliness about the cow barns, though it will be impossible for him to inspect the actual process of milking in more than two places in one day. Time will be lacking for him to detect tuberculosis in the early stages in either man or beast, and he can only surmise from the general appearance of the place that the milk cans are properly cleansed in boiling water. If he is conscientious and filled with enthusiasm, he may do good missionary work, but the inculcation of habits of cleanliness in the average farm hand, who hardly knows the meaning of the word and is a stranger to all it implies, will be a work of time—and in the meanwhile the rivulet of milk from this contaminated source will carry its dirt and its germs of disease to foul the great river of 400,000 gallons which flows into the city at every dawn.

We do not belittle the value of the inspection of milk by the health authorities of this city. It is absolutely necessary as a sanitary measure, and its place cannot be filled by pasteurization. Pasteurization alone, for which the newspapers are crying, is insufficient; the milk that is pasteurized must be reasonably pure if the finished product is to be accounted safe. The process destroys the pathogenic bacteria present in the milk, but it does not affect the toxins already elaborated by these germs, and these toxins are poisons that may cause sickness and death. In the course of time—years it may be—the needed reforms in milk protection may be effected by the system of inspection; but only after repeated warnings and punishment by rejection of the milk will the honest farmer be gradually brought to a realization of the fact that obvious filth is objectionable and doesn't pay. Inspection is necessary and will doubtless, if conscientiously performed, bring about in the course of time betterment in the milk supply; it can never make it perfect, and so long as a great part of the supply is derived from small farms with one to half a dozen cows, where economic conditions and tradition render scientific methods impracticable, if not impossible, it will be safer for the babies of this city if the essential inspection of the sources is supplemented by pasteurization of all milk sold, let us say, at less than ten or twelve cents a quart. Such a price limit will exempt the product of the certified dairies from the necessity of pasteurization, and those who believe in the nutritive superiority of raw milk will be able to get what they want if they can afford to pay for it. Others, under a system of conscientious inspection and pasteurization, will be assured that the milk offered for their consumption is, if possibly not so nutritious, at least free from the germs of disease—a food and not a poison.

AN IMPORTANT DECISION REGARDING THE PRACTICE OF MEDICINE.

The Appellate Division of the Supreme Court of this State has recently handed down an opinion affirming the conviction of a self-styled "mechano-neural therapist" of the illegal practice of medicine. The appellant contended that he was not guilty of the crime charged, namely, of practising medicine without being lawfully authorized and registered, inasmuch as he was not practising medicine within the meaning of the statute, in that he neither gave nor applied drugs or medicines nor used surgical instruments. In his comment upon this contention Justice Clarke said:

"To confine the definition of the words 'practice medicine' to the mere administration of drugs or the use of surgical instruments would be to eliminate the very cornerstone of successful medical practice, namely, the diagnosis. It would rule out of the profession those great physicians, whose work is confined to consultation—the diagnosticians, who leave to others the details of practice. It is a well-known fact that the disease popularly known as consumption may, if discovered in time, be arrested, if not entirely eradicated from the system, by open air treatment in the proper climate, and that in such cases use of drugs has been practically given up. Would the physician, in such a case, who by his skill discovered the incipient disease, advised the open air treatment, and refrained from administering drugs, not to be practising medicine? It may be difficult by a precise definition to draw the line between where nursing ends and the practice of medicine begins, and the Court should not attempt, in construing this statute, to lay down in any case a hard-and-fast rule upon the subject, as the courts have never undertaken to mark the limits of the police power of the State or to have precisely defined what constitutes fraud. What the courts have done is to say that given legislation was or was not within the limits of the police power, or that certain actions were or were not fraudulent."

The appellant had relied upon the case of Smith *vs.* Lane, which was an action brought to recover a sum which it was alleged the defendant had agreed to pay the plaintiff for treatment of certain bodily disabilities by means of manipulation. The referee dismissed the complaint because the plaintiff was unauthorized to practise medicine or surgery. The case was appealed and the judgment was reversed, Justice Daniels holding that what the man did in no just sense constituted the practice of either medicine or surgery. This was, however, a private contract to perform certain services for a certain sum, and the public was not represented, and Justice Clarke was of the opinion, based upon the general current of the authorities throughout the country, and upon an examination of the history and growth of our own public health statutes, that the rule as claimed to have been laid down in Smith *vs.* Lane could not here apply.

"When we find," he concluded, "as in this case, a defendant holding himself out by sign and card as a doctor, with office hours, who talks of his patients and gives treatments, who makes a diagnosis and prescribes diet and conduct and remedies, simple though they be, and who asserts the power to cure all diseases that any physician can cure without drugs, and also diseases that they cannot cure with drugs, and who takes payment for a consultation wherein there was an examination and determination of the trouble—that is, a diagnosis—as well as payment for subsequent treatment, even if no drugs are administered, we must hold that he comes within the purview of the State prohibiting the practice of medicine without being lawfully authorized and registered."

The importance of this opinion is greater than may be apparent to those who do not know the difficulty that is often encountered in securing the conviction of an illegal practitioner through the absence of any judicial definition of what constitutes the practice of medicine and surgery. Mr. Champe S. Andrews, counsel to the Medical Society of the County of New York, has for years been trying to get some court of record to define the practice of medicine. Though there have been a number of appeals to the Appellate Division, the question was never squarely raised there until the present case. This opinion at last substantially establishes such a definition, which will do more to help the County Society in its war against irregular practice and quackery than can readily be imagined.

THE MANNER IN WHICH TUBERCULOUS INFECTION OF THE LUNG TAKES PLACE.

The question of why the pulmonary apices should form sites of predilection for the growth of the tubercle bacillus has given rise to much controversial writing and many observers have endeavored to furnish a plausible explanation of this clinical fact. There are weak places in most of the hypotheses that have been suggested, however, or at least no one of them has seemed sufficiently well grounded to justify its universal acceptance. This is perhaps in some measure due to the fact that it is still by no means settled in just what way the infection of the lung takes place, for all the possible avenues through which invading organisms can be conceived of as approaching the lung have been championed by different investigators who have each been able to advance arguments of more or less validity in favor of their views. Most of the current theories are subjected to a critical analysis by Tendeloo of Leyden (*Münchener medizinische Wochenschrift*, January 15, 1907), who rejects the hematogenous theory, the theory that tubercle bacilli become entangled in the nasal passages, are swallowed with the nasal mucus and then find their way to the lungs via the mesenteric lymph nodes, the belief that infection of the lung may occur through the cervical lymphatics, etc., and adheres to the older view that the infection is, in most cases, excluding general miliary infections, the result of the deposition in the lung of tubercle bacilli taken in with the inspired air.

The special proneness of the upper and posterior portions of the lung to form the starting points of the tuberculous process is explained by considering the fate of the pigment particles that are constantly being inhaled and that are found in such large quantities deposited in the lungs of all

city dwellers. The pigmentation is most pronounced in the upper and posterior parts of the lung, and this is because in these regions the lymphatic stream whose function it is to carry away the foreign particles is most sluggish. The slowness of the current is largely dependent on the fact that in this part of the lung there is least respiratory activity and consequently the conditions are not favorable to the movement of the lymph through its channels. For this reason any tubercle bacilli which have entered the lung and are being swept on by the lymphatic stream in attempt to prevent infection are likely to become arrested at these points and be enabled to proliferate. This is all the more likely to be the case because it has been shown that tubercle bacilli do not grow well in a moving current of broth. The reduced respiratory activity in and near the apices also encourages the deposition in these situations of tubercle bacilli that may have been borne in by the inspired air, and it is to the author's belief that primary pulmonary tuberculosis is usually the result of an aërolymphogenous infection.

This is merely the outline of Tendeloo's very detailed dissertation, and while perhaps it presents nothing actually new to most readers, it is interesting because it forms a comprehensive and critical survey of much of the modern work in this highly important field. In connection with Tendeloo's statements in regard to the pigment deposits one is reminded of the importance that has been ascribed by Hodenpyl, and more lately by Ribbert, to these same lesions.

SUBGLOTTIC LARYNGOSCOPY.

Attempts have not been wanting to perfect the technique of laryngoscopic examination in one respect in which it has always been deficient. The ordinary mirror affords a satisfactory view of the parts above the glottis and of a small portion of the beginning of the trachea, but the lower surface of the vocal cords and the parts immediately adjoining have been inaccessible to the eye of the examiner. Several instruments have been designed to overcome this deficiency in the armamentarium of the laryngologist, notably by Rosenberg, Mermod, and Kuile, but apparently their apparatus has been lacking in either simplicity or ease of operation, so that their methods have not come into any great popularity. Gerber, however, has devised an intralaryngeal mirror which seems to promise better things. In its perfected form (*Monatschrift für Ohrenheilkunde*, 1906, No. 10) it consists of an oval mirror measuring 10 mm. in its longest diameter, affixed to a handle having the form customary to instruments intended for intralaryngeal use. The mirror is so arranged that it is introduced between the well-cocainized vocal cords in the vertical position and can then be made to assume a position more or less nearly approaching the horizontal by means of a suitable mechanism. The image formed in this small mirror is viewed in the ordinary laryngoscopic mirror.

Gerber has reported only one case in which information was obtained by means of the new instrument which could not have been secured in any other way, but this is perhaps owing to the infrequency of suitable cases rather than to any inadequacy of the method. The patient in point was a man suffering from hemoptysis, the cause of which remained a mystery until by means of the subglottic laryngoscope a varicosity, which by repeated ruptures had given rise to the hemorrhages, was discovered on the under surface of the right vocal cord. The same procedure has been successfully applied by Max Senator, who in the *Berliner klinische Wochenschrift*, January 21, 1907, describes the case of a tenor of considerable reputation, whose vocalization had become seriously impaired through lack of purity in the upper register, particularly in the falsetto notes. The ordinary laryngoscopic examination revealed a very slight thickening of the edge of one vocal cord, but it was not until an examination had been made with the subglottic laryngoscope that it was discovered that the source of this thickening was a minute new growth surrounded with dilated blood-vessels situated on the under surface of the vocal cord. The growth was successfully removed by cauterization and the singer's voice restored to its former quality. Although, no doubt, the experienced laryngologist can in most cases dispense with the use of a second mirror of this sort—and the technical difficulties in its use will probably restrict the subglottic laryngoscope to the hands of only the most expert—in exceptional instances such as those recorded it is quite conceivable that the instrument should prove of much practical utility.

Nonsurgical Treatment of Appendicitis.

In view of the almost universally accepted dictum that appendicitis is from the beginning a surgical disease, and that the time to operate is immediately, it is not without interest to read a communication from a clinician who takes the opposite standpoint, and is able to justify his position with statistics. Pfister, in the *Deutsche medizinische Wochenschrift*, January 10, 1907, deprecates early operation in the average case, and gives a résumé of seventy cases treated expectantly in the medical department of the University Hospital at Heidelberg during the past two years, in order to illustrate the safety of this plan. The seventy cases included thirty of slight severity, twenty-five of medium gravity, and fifteen serious cases. In this series all the patients were discharged free from symptoms, except one, who died after transfer to the surgical side, though, as there was delay in operating after the transfer had been made, this death cannot be charged to the medical treatment. Four other patients were transferred to the surgical service and operated on, but the remainder recovered under purely medical treatment. The author's position is that all cases of appendicitis that do not from the first create an impression of great severity should be treated with opium and the ice bag, though, of course, if beginning peritonitis or perforation is suspected immediate operation is required. Otherwise, surgery should be resorted to only if the condition is distinctly becoming aggravated, or if recovery is slow and there is delay in the absorption of the exudate or persistent pain. If attacks recur the interval operation is to be recommended. If it were likely that Pfister's statistics could be duplicated regularly there would be little ground for criticism of his recommendations, but if the history of appendicitis has taught any one thing with especial insistence, it

is that the disease is essentially a treacherous one, prone to abrupt changes for the worse, and oftentimes manifesting lesions out of all proportion to the symptoms or physical signs. It typifies to the extreme the Hippocratic apothegm that experience is fallacious and judgment difficult, and until more accurate means of diagnosis shall have been evolved we believe that all surgeons and most medical men will concur in advising early operation.

Pancreatic Diabetes due to Autoinfection.

The pathology of the pancreas has especially in late years interested various observers. Among the recent writers and investigators on this subject are Lancereaux, Gellé, Oser, and Opie. No one disputes at the present day the frequency and importance of pancreatic lesions in diabetes. A. Gilbert and P. Lereboullet in the *Revue de Médecine* of November 10, 1906, present an interesting contribution to the study of pancreatic diabetes due to autoinfection. The nature of these lesions, say these writers, has been clearly determined, thanks to the knowledge of the structure of the pancreas; and a particular significance is attributed to the alterations in the islands of Langerhans which are regarded by some authorities as the agents of the internal secretions of this organ. Gilbert and Lereboullet, from the numerous anatomical and clinical facts which they have observed during their study of this subject, are impressed with the great importance of the alteration of the pancreas. They believe that diabetes when it is not severe, and when it shows the characteristics of that form of diabetes called by the French "arthritic" is often of pancreatic origin. The pancreatic change consists of a sclerosis, inter- and intraacinous, which ordinarily but not constantly or exclusively attacks the islands of Langerhans. If the characteristics of this pancreatic sclerosis are analyzed it is often observed that there exists a sclerosis of canalicular origin due to an ascending infection. The infection appears to be a primary autoinfection, the development of which is explained by the predisposition of the patients to digestive autoinfections. The proof of this predisposition is found in their personal and family antecedents and in the anatomical study of the various digestive organs which show the lesions of canalicular inflammation. The lesions of autoinfection of the pancreas produce effects only when the gland is involved seriously. This explains why diabetes appears frequently only at an advanced age. Diabetes results in these cases from a hyperfunctioning of the liver. Inversely one can conceive theoretically of a diabetes due to hepatic insufficiency consecutive to hyperfunctioning of the pancreas.

The Specific Gravity of Urine.

In a recent letter to the *Lancet* (January 26) Dr. A. W. Brand calls attention to the fact that the specific gravity of the urine varies greatly with its temperature. He notes that probably in the great majority of cases specimens of urine are examined when it has become cooled—*i.e.* when it is at the temperature of the surrounding air, since these specimens generally reach one in bottles which are allowed to stand some little time—but he has frequently had occasion to examine urine which has been freshly passed, notably in cases of examination for life insurance, when it is voided at the time of examination. He has often been struck with the low gravity of such freshly passed urine in many cases of young and healthy lives and has been disposed to attribute it to the influence of the ingestion of fluid previous to the examination. On one occasion, lately, a specimen showing a specific gravity of 1015, when freshly passed, was left standing over night, with the urinometer *in situ*. On looking at it next day, before emptying the test glass, he was surprised to find the specific gravity to be 1020, thus showing a rise of five points. His attention being thus directed to this discrepancy, he made a series of observations, noting the temperature and specific gravity of the urine when it was freshly passed, and later when it had cooled down to the temperature of his surgery. As a result he found that the specific gravity of urine varies inversely with the temperature and that it rises, on an average, one point for every fall of eight degrees of temperature. He says he has found no allusion to this in any text-book of physiology or clinical medicine, and he considers the recognition of the fact is of importance. Urine which at 60° F. shows a specific gravity of 1020, will at 96° show one of only 1015.

News of the Week.

Public Lectures on Insanity.—Dr. C. L. Dana will deliver the third of the series of public lectures on the above topic, arranged for by the Psychiatrical Society, at the Academy of Medicine, 17 West Forty-third street, on Saturday, February 16, at 8:30 P.M. The subject will be: "The Facts of Heredity and Their Relation to Mental Disorders." These lectures are intended to place before the medical profession and the general public facts with regard to mental disorders which indicate the possibility and duty of initiating a wide movement towards general preventive measures.

Report of the State Board of Charities.—The report of the State Board of Charities shows that in 1906 the State appropriated $1,945,089.27 for the charitable institutions, of which amount $1,347,271.32 was for maintenance and $428,375 for extraordinary expenses. It recommends for 1907 that the Legislature appropriate for maintenance $1,415,000 and for new buildings and improvements $467,920. There were 30,618 dependent children remaining in institutions at the close of the fiscal year, an increase of 371. During the year 18,119 had been discharged. During the last ten years the number of institutions for dependent children has remained practically the same, but the population has slowly increased from 27,769 in 1896 to 30,618 in 1906. The larger proportion of these children are in institutions in and about New York City, all under private control. There were 7,753 inmates in the alsmhouses of the State at the close of the fiscal year, and the number seems to be increasing. Among the recommendations the board advises the establishment in the eastern part of the State of a custodial asylum for demented epileptics and feeble-minded persons who cannot be properly cared for in the existing institutions, and of a hospital pavilion for the Soldiers and Sailors' Home.

Report on Milk Supplies.—A committee of five of the New York Association for Improving the Condition of the Poor, having Dr. R. G. Freeman as its chairman, has issued a report on the milk supply question in this city. In it the importance of inspection of dairies and creameries is upheld, and it is stated that eighty more inspectors are needed to do the work for this city. The conditions under which the milk should be produced and

handled are detailed and it is emphasized that inspection must then follow the milk every step of the way to the consumer, protecting it from contamination and never permitting its temperature to rise at any stage above 50° Fahrenheit. The expression was unanimous that nothing can render such inspection unnecessary or reduce its importance. The establishment of infants' milk depots is considered of prime importance. The committee declares for a campaign of education on the value of protecting milk and favors legislation regulating its sale. A milk committee of thirty-eight members has been appointed to continue the efforts to improve the quality of the city's milk.

Control of Tuberculosis.—In the report of the subcommittee of the Charity Organization Society appointed to consider the tuberculosis question in this city it is estimated that the number of tuberculosis cases in Manhattan in 1910 will be 19,596 and that dispensary provision should be made for 4,626 of these. It is also estimated that for the treatment of the tuberculous poor 2,734 hospital beds will be required and that the cost of maintaining the system of dispensaries and the hospitals will be $1,269,400. The report states that the treatment of the tuberculous poor of the city is being carried on by three city departments, each acting independently of the other, and that there are five public and four private special dispensaries giving treatment. The committee suggests a plan for the centralization of the efforts to combat the disease. This plan calls for the establishment of fifteen dispensaries and for a central distributing tuberculosis hospital, on the river front on the Bellevue Hospital grounds. It is recommended that a special Board of Tuberculosis Hospitals be formed to consist of the Commissioner of Charities, the president of the Bellevue and Allied Hospitals Board and the Commissioner, or the chief medical officer, of the Board of Health, which shall have entire supervision of the management of the central hospital and dispensaries.

New Bellevue Hospital Plans Filed.—Plans for the six-story and basement pathological building which is to form the northwestern section of the new Bellevue Hospital have been filed by the architects, McKim, Mead and White. The pathological building is to cost $800,000 and will have a frontage of 142 feet and a depth of 120 feet, with a main entrance facing the south. The building is to be of ornamental brick, with a base of granite and trimmings of limestone. The second story will contain the pathological museum and a series of autopsy chambers. The third and fourth stories will be fitted with laboratories, the fifth will contain the library, and on the sixth will be special laboratories for bacteriological experiments and special photography work. On the roof will be the animal operating room and three rooms for the observation of inoculated animals. Each of the five upper floors will also contain dormitories for the hospital attachés of the various departments.

Osteopathy Bill.—The osteopathy bill now before the Legislature differs in some respects from those that have been previously presented. It creates a board of osteopathic examiners under the public health law, the provisions following those of the State medical examining boards, excepting those referring to materia medica and therapeutics, and substituting the theory of osteopathy and its practice. Provision is made for the appointment of the osteopathic examining board by the Regents, and all osteopathic schools are to be under the regulation of the Regents. Dr. Arthur S. Root and Albert Vandeveer of Albany have appeared before the Senate and Assembly committees on public health in order to oppose the passage of the bill.

Legislation in Pharmaceutical Matters.—Representatives from pharmaceutical organizations and schools of the State are in Albany for the purpose of discussing the pending pure food legislation. They will vigorously support the measure regulating the sale of cocaine in any form or compound, and have also decided to take steps to include in one measure all the bills affecting pharmacy before the Legislature and to make this measure conform to the national pure food law.

New York State Child Labor Bill Passed.—The Senate has passed Senator Page's bill carrying out Governor Hughes' recommendation that children employed in factories should have an eight-hour workday. The bill provides that no minor under sixteen years of age be employed, permitted, or suffered to work in any factory before 8 o'clock in the morning or after 5 o'clock in the afternoon of any day, or for more than eight hours in any one day.

For State Ice Inspection.—Dr. E. H. Porter, State Health Commissioner, has sent to the Legislature a request for a larger appropriation than the $57,000 the department received last year, in order that a systematic inspection of the ice fields on the Hudson and in the Adirondacks may be instituted. The present resources of the department do not permit the proper safeguarding of the ice supplies.

Pure Food and Drug Bill for Illinois.—In the lower house of the Illinois Legislature Representative Lindly has introduced a pure food bill at the instance of Pure Food Commissioner Hanby Jones. The bill covers both food and dairy products, and proposes in some cases stricter regulation of food stuffs than is attempted in the national pure food bill, which it proposes to supplement by giving State application. It provides an annual appropriation of $125,000 for the enforcement of the law. The standard of purity for drugs is that adopted by the United States Department of Agriculture, and it is stipulated that where no standard has been adopted by that department, then the standard shall be that given in the last edition of the United States Dispensatory. Definitions of adulteration and misbranding follow closely the requirements of the national act, and explicit restrictions are made in the use of drugs in the manufacture of liquors.

The Oak Park (Ill.) Hospital and Training School for Nurses is said to be the most complete institution of its kind in Illinois. It will be dedicated in March. The structure will have a capacity of sixty patients. Ready for occupancy the building will have cost $150,000. The operating rooms are two in number and are lighted by large north windows and skylights. The floors are of white tile and the walls are wainscoted with heavy white plate glass to a height of seven feet. The hospital grounds contain one acre, the money for which was raised by Dr. J. W. Tope of Oak Park. About $5,000 additional for the equipment of the surgical department was secured by the physicians of the staff. The balance of the construction fund was supplied by the Sisters of Misericordia.

Infectious Diseases in Chicago.—The Chief Medical Inspector of Chicago, Dr. Heman Spalding, reports that "during the week 292 cases of diphtheria were reported to the Department of Health, being six fewer than were reported the

previous week. In the same time 1,080 cases of scarlet fever were reported—an increase of 681 cases over the preceding week, and 190 cases of measles were reported—an increase of fifty-one. The 350 newly appointed medical inspectors in their visits to schools have uncovered a large number of cases unattended by physicians and unreported to the department. In numerous instances they have found children in school recovered from a mild attack of scarlet fever and still in an infectious condition. Numerous instances were found in which children were in school coming from a house where a mild case of scarlet fever existed unattended by a physician. The finance committee has recommended the erection of a municipal hospital for infectious diseases. This hospital is an absolute necessity, and the lack of it has long been a reproach to the city."

A Testimonial to Dr. Pardee.—The Alameda County (Cal.) Medical Society, on January 28, tendered a banquet to ex-Governor Dr. George C. Pardee, one of its members, to commemorate his return from official life to the profession. About fifty members of the society were present. Dr. D. Crosby, president of the society, served as toastmaster, and Dr. Charles A. Dukes, the treasurer, as chairman of the committee of arrangements. Responses were made by Drs. Hubert N. Rowell, D. D. Crowley, George C. Pardee, N. K. Foster, Secretary of the State Board of Health, Frank Adams, and J. Maher. After the banquet a general reception was held, in which many others came to renew old friendships and to express appreciation of Dr. Pardee's faithfulness to his profession while serving the State.

Paths and By-Paths in California.—The naturopaths, the osteopaths, and even those of the "straight and narrow" path are besieging the State Legislature for more law. They want recognition as distinct schools of practice. The law recognizing osteopathy was recently declared to be unconstitutional. The State Board of Medical Examiners, it is understood, is preparing a bill which, if made law, will admit to it an osteopath and do away with the examination in materia medica and therapeutics. The members of all schools will then be required to pass the same examination in anatomy, chemistry, physiology, bacteriology, pathology, toxicology, surgery, obstetrics, and probably other branches.

Antivaccination in California.—Now that a layman has become Governor of the State, the antivaccinationists are making strenuous efforts to have the law repealed which requires all school children to undergo vaccination. Two years ago they were successful in having a bill pass the Legislature, but met with defeat at the hands of the Governor, Dr. George C. Pardee, who could not conscientiously attach his signature.

Bequest to the Pasteur Institute.—It is announced that the Pasteur Institute of Paris is to receive the sum of $5,000,000 bequeathed to it by the will of the late Daniel Osiris. In addition to other public benefactions, Mr. Osiris in 1899 presented to the Institute of France a sum representing an annual income of about $6,500 for a triennial prize of $20,000, open to citizens of all countries, for the most remarkable work or discovery of general interest, especially in the fields of surgery and medicine.

A Monument to Theodor Schwann.—On December 7, 1910, a century will have elapsed since the founder of the cellular theory was born at Neuss on the Rhine. His native town has decided to honor his memory by the erection of a monument to be unveiled on that day with suitable ceremonies. The medical profession is under a deep obligation to this investigator, who laid the foundations on which our present concepts of disease are so largely based, for he was a worker no less successful than indefatigable in the domains of histology, physiology and biology; an authority on the processes of fermentation, decomposition, spontaneous generation, and digestion, and last, not least, the discoverer of pepsin. His master, Johannes Müller, and his collaborator, Schleiden, have lately been honored by the erection of statues in Coblentz and Jena, respectively, and the members of the medical profession are invited to contribute to this memorial to Schwann. Communications are to be addressed to: Schwanndenkmal Städtische Sparkasse, Neuss am Rhein, Germany.

Health Conditions in Panama.—The report of Col. W. C. Gorgas for the month of December has been made public by the Isthmian Canal Commission and shows that health conditions continue excellent in the canal zone. In the total force of 8,200 whites there were eight deaths, giving a rate for the year of eleven per thousand. Of these whites 6,000 are Americans. Among these Americans there were no deaths from disease. There are 800 American women and children, the families of these 6,000 employees, and among them there was no death from any cause. The death rate among the general population has also been satisfactory. In the town of Colon in November there were 77 deaths, in December 48. The sick rate among the employees was about what it was in the previous month, thirty per thousand. During the month no quarantinable disease of any kind was reported.

Warning Against the Dangers of Spitting.—The school children of Brooklyn have been provided by the Board of Education with Board of Health circulars setting forth the dangers of spitting in public places. The circular is printed on gummed paper, so that it may be posted inside the back cover of the school books.

Cigarette Smoking by Youths.—The Illinois Senate has passed a bill prohibiting persons under eighteen years of age, pupils in schools, and students in universities from smoking cigarettes in any public place.

Grip is reported to be so common in Paris that the postal authorities have issued a notice that certain deliveries of mails have been suspended owing to the prevalence of the disease among the postmen.

Prof. Behring of Marburg has issued an open letter to the press in which he indignantly denies the reports that he is suffering from insanity, or is on the verge of a mental breakdown, and charges that the reports were fabricated by his personal enemies with the object of injuring him.

Medical Men Popular in Germany.—A popular newspaper vote taken in Germany on the twelve greatest Germans now living accorded to Dr. Robert Koch, Professor Ernst Haeckel, Professor Konrad Röntgen and Professor Ernst von Behring, respectively, the third, fourth, fifth and eleventh positions in this list.

Dr. Alvah H. Doty has been reappointed as Health Officer of the Port of New York, a post he has held since 1895.

Dr. W. Freudenthal, of this city, requests us to add to the report of the meeting of the Section on Public Health of the Academy of Medicine, published in the MEDICAL RECORD of February 2, that he also participated in the discussion pertaining to the health of New York City.

Fasting for Pleasure and Profit.—What is asserted to be the world's record for fasting has been made by Sacco, the Hungarian professional faster, who has completed an exhibition test in London lasting forty-six days and four hours. His wish to continue and complete a period of fifty days could not be carried out on account of extreme weakness. The newspapers also report the voluntary fast of a Toledo, O., physician, who is stated to have taken no food and no liquid but water during thirty-four days.

St. Gregory's Hospital.—The State Board of Charities has granted a charter to St. Gregory's Hospital on Gold street, which was taken over several months ago by the Volunteers of America and is now managed by that organization. An application will now be made to the police to set aside a separate ambulance district for the hospital.

Beth Israel Hospital has received the sum of $21,000 contributed by guests at a recent dinner given by the directors and medical staff in honor of the president of the hospital, Joseph H. Cohen.

Bequests.—By the will of Lady Martha E. Kortright, who died recently at Florence, Italy, personal property valued at $100,000 is to be divided equally among the following beneficiaries: Presbyterian Hospital of Philadelphia, Board of Education of the Presbyterian Church in the United States, Presbyterian Board of Relief for Disabled Ministers and Orphans of Deceased Ministers, and the Board of Home Missions of the Presbyterian Church in the United States.

International Congress on School Hygiene.—The preliminary program of the second International Congress on School Hygiene, to be held on August 5-10, 1907, at the University of London, South Kensington, has been issued. The work of the Congress will be divided into eleven sections, each presided over by an authority on the subject dealt with. The president of the Congress is Sir Lauder Brunton, F.R.S., and the secretaries are Dr. James Kerr and Mr. E. White Wallis.

Republican Valley (Neb.) Medical Association.—Officers were elected as follows at the recent meeting of this society: *President*, Dr. Cone, Oxford; *Vice-President*, Dr. Sherick, Bertrand; *Secretary*, Dr. Campbell, Stamford; *Treasurer*, Dr. Sunbury, Holdrege.

Medford (Mass.) Medical Association.—The following are the recently elected officers of this organization: *President*, Dr. J. Walter Bean; *Vice-President*, Dr. Norman F. Chandler; *Secretary and Treasurer*, Dr. Frank S. Smith.

Obituary Notes.—Dr. Robert T. Wood of Paris, Ky., died on January 26 at the age of fifty-four years. He had been in poor health for some time, but had lately been able to resume his practice and his death was unexpected. He was a graduate of the Ohio Medical College and had practised in Paris since 1881.

Dr. George H. Thoma of Reno, Nev., died of cerebrospinal meningitis on February 1 at the age of sixty-five years. Dr. Thoma was a native of Montgomery county, N. Y., and studied medicine in the Albany Medical College. He served as assistant surgeon through the Civil War. He settled in Austin, Nev., in 1867, and twenty years later removed to Reno, where he had practised ever since.

Dr. O. M. Sheridan of Roxbury, Mass., died on February 2 at the age of forty-three years. He was born in Randolph and was graduated from Boston college in 1885. Three years later he received his medical degree from the New York University Medical School.

Dr. R. P. Comfort of Nashville, Mich., died on January 27 at the age of fifty-nine years. Dr. Comfort was born at Moscow, Mich., and received his degree from the Michigan University Medical School. He had practised at McBrides, Mason and Hudson, and for the past fifteen years in Nashville.

Dr. August L. Justice of El Paso, Tex., died on January 30 at the age of sixty-six years. He was born in Virginia and after serving in the Civil War studied medicine in Rush Medical College, Chicago. After practising for some time in Denver and Santa Barbara, he finally settled in El Paso in 1881.

Dr. David A. Collins of Roxbury, Mass., died on February 5 at the age of forty-four years. He was graduated from Holy Cross College in 1882 and four years later received his medical degree from the Harvard Medical School. He had practised in Roxbury for over ten years and was medical supervisor of the Eliot School District.

Dr. A. C. Sinclair, formerly of Winnipeg, died on January 23 at Colborn, Ont. Dr. Sinclair was born in Glengarry county seventy-seven years ago and had practised in Toronto, Winnipeg, and Rossland, B. C.

Dr. William J. Chappell of Baltimore died suddenly on February 7 at the age of forty-nine years. Dr. Chappell was graduated from a Baltimore medical college in 1884 and had practised in that city ever since.

Dr. Everett H. Merwin of Kansas City, Mo., died suddenly on February 9 at the age of thirty-eight years. Dr. Merwin received his medical education in London and had spent several years on British steamships as surgeon. He was treasurer of the Kansas City Homeopathic College.

Dr. Wm. C. Pickett, Professor of Diseases of the Mind and Nervous System in the Medico-Chirurgical College, died at Aldan, Delaware county, Pa., on February 6 at the age of thirty-eight years. He was born in Meadville, Pa., and was graduated from Jefferson Medical College in the class of 1889. He was successively surgeon to the schoolship *Saratoga*, resident physician in the Philadelphia General Hospital, resident physician in the Insane Department of the Philadelphia Hospital, demonstrator of neurology in Jefferson Medical College, and visiting neurologist to the Philadelphia Hospital.

Dr. Franklin Wheeler of Farmington, Conn., died on February 10, aged eighty years. He had been physician at the Porter School in Farmington for over forty years.

Correspondence.

A SINGLE EXAMINING BOARD FOR NEW YORK STATE.

To the Editor of the Medical Record:

Sir:—Year after year the medical profession of New York has been called upon to oppose the passage of laws creating State Examining Boards in osteopathy, dermapathy, optometry, and so on. Year after year we have succeeded in convincing the legislature that the passage of such laws would be unwise; but in answer to the inquiries of Senators and Assemblymen, "what are you going to do with these people who besiege us each year?" we have answered: "Let them comply with the present law and then practise any method they choose." Then has come the second prtinent query: "The homeopaths have a separate board, why should not the osteopaths be granted the same privilege, if they will comply with all the requirements excepting treatment?" As the result of all this

a bill has been drawn up, which is indorsed by the State Department of Education and many leading members of the legislature, accurately defining the practice of medicine and providing for a single examining board, before which all who desire to practise the healing art must come and pass a common examination, eliminating the subject of practice, assuming that all who have the other necessary qualifications will be able to practise intelligently the method which seems to be indicated in the cases they meet.

It is not expected that the enactment of this law is going to bring about an immediate leveling of all the barriers now existing between "allopathic," homeopathic, and other "pathic" physicians, although doubtless that will be the ultimate result. Nor will it prevent the demands in the future of peculiar classes desiring separate recognition for commercial and other reasons. It will, however, place the legislature in a position to say, when future efforts to secure class legislation along medical lines are made, that the State of New York recognizes only the ordinary educated physician, and the method of practice is something the individual physician must determine for himself. It will place medical practice in a higher plane than has heretofore been accorded it, and will accomplish what our present law was designed to do, and has failed to do, namely, properly protect the people of the State of New York from incompetent physicians.

Will you please request your readers to write their representatives in the Legislature at once urging the defeat of osteopathy, optometry, and all similar bills, and the passage of the single board bill, which is Senate Bill No. 154; Assembly Bill No. 160, and to use these numbers when writing.

FRANK VAN FLEET, M.D.

Chairman Committee on Legislation of the Medical Society of the County of New York.

HEADACHE AND EYESTRAIN.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—An article under the above caption by Dr. George M. Gould, in the *Journal of the American Medical Association* of November 10, 1906, caught my eye, and greatly impressed me. I was struck by his indictment of the profession for the "narcotism," as he styled it, of its members. What attracted me most forcibly was his statement that ophthalmic specialists denied the effect of eyestrain in causing headaches and other bad consequences. The general practitioner might be excused for a certain degree of ignorance of such results of defective vision, for he usually has no means of ascertaining or measuring it, nor would he know how if he had. But that specialists generally should scout so evident a fact seems to me extraordinary. That eyestrain causes headaches is well known to even many of the laity, for they have the knowledge based on personal experience, having proved the pudding by the eating of it. Their acquaintances are told of it, and believe it. Many of them, in turn, go to the optician for relief—and get it. So much the worse for the doctor who is ignorant or prejudiced.

"Are our eyes getting worse?" is the query heard from many in view of the increasing prevalence of spectacles. By no means. As evolutionists we must believe that they are gradually growing better in each succeeding generation. Why, then, so many eyeglasses or spectacles? Merely because there are so many defective eyes. Nor are these statements irreconcilable. We use the eyes more now than formerly in a way to bring out their defects. The illiterate day laborer usually is without glasses until he becomes a marked presbyope quite late in life—at least late for his class, for they age sooner than do those more favored by occupation and environment. If he learns to read and write, and scans the paper daily, he wears glasses sooner. The illiterate woman likewise first wears glasses for presbyopia late in life unless she darns socks, sews, or does other near work requiring distinct vision, in which event she begins the use of them earlier. A fine sieve is not needed to screen coarse coal. Even a perfect eye requires aid when the object to be seen is very minute. Hence the microscope. Who could do without its aid to see the minute world it reveals? Are our eyes degenerating on that account? It is a question of degree on the one hand, and of defects on the other. A bundle of mail, such as is usually handled by letter-carriers, is not very heavy for the ordinary man, but it feels heavier the longer it is borne. These men are not losing strength because they avail themselves of a bag slung over the shoulder to ease the burden. Nor is civilized man becoming weaker because he uses a chair with a back against which he can comfortably lean, rather than sit on an old-style four-legged stool without this restful addition.

Considerable derision first met the systematic examination of the eyes of school-children, and even of many corporation employes. Yet no one realizes better than the child with its first set of glasses how it eases the work and brightens the world. I am not an ophthalmologist, but a general practitioner. Nevertheless, I do look into eyes that seem to me to need it, and I test them for errors of refraction, and I prescribe glasses when satisfied that I know what I am doing. When in doubt, I send them to the specialist. Many a child has been made happier by me for detecting and correcting defective vision. An occasional dunce in school is so because he cannot see his work on either the blackboard or desk. How can he become interested or learn under the circumstances except by the little that filters in through the unusual channel of the ears?

Why do school-children find glasses so useful only to discard them after leaving school? Simply because they have greater need for them while studying. The younger the child, the more does its greater illiteracy require visual accuracy to distinguish the separate letters of each word, which it can identify and pronounce only after analysis into its component parts. As its familiarity with smaller words grows, larger ones are continually being learned while the memory gradually acquires a hold upon the smaller and earlier learned word forms. As the child progresses in its studies, it reads more, then begins to write and to manipulate figures. Arithmetic is a greater strain than reading, because each figure must be carefully noted. Penmanship is also a strain upon the eyes. When the pupil is far enough advanced to read by word forms and write automatically, the lessons at school and the home work in reading, figuring, and composition keep up an increased demand upon the muscles of accommodation, so that it is a wonder that even a perfectly normal eye does not tire and make itself known in some disagreeable way. Add to all this required strain the reading of books and of newspapers, and the wonder is that so many get along as well as they do without glasses.

So much for the simple defects of vision that are correctable by the accommodation, vision equally deficient in all meridians. The muscles make a successful effort, being rewarded by corresponding easement and clearness of vision. When, however, the defect is meridianal, efforts at accommodation aggravate the trouble, for the correction of the defect produces a corresponding disturbance of the opposite meridian. If there is relaxation, the original trouble reappears. Thus may the accommodation find itself seesawing back and forth betwixt the devil and the deep sea, or the proverbial two horns of a dilemma, every effort worse than useless, for the muscles become tired, the vision remains defective, and annoying reflexes follow. Eye quacks are reaping a harvest, and the general practitioner loses his opportunity because of failure to recognize these facts and act accordingly.

I would advise all physicians to get some good book on the eye, and then a set of test lenses and cards, an ophthalmoscope, and a retinoscope. They should carefully read the book, especially the part explaining the physics of refraction, before going further into the subject. Then practical instruction should be sought in the use of these implements, if only for a week. Work should be done under a mydriatic of short effect. To attempt this kind of work without it is folly except for the expert.

A patient never comes to me complaining of habitual headache (man, woman, or child) without a prompt inquiry into the ocular sufficiency. It is the rule to find refractive defects that are proven the cause of the trouble because of its prompt disappearance upon the use of suitable glasses. I could turn to my histories and cite scores upon scores of cases, but the list would be monotonous and a waste of space. To the doubter I simply say, examine your patients and see for yourself. If you cannot do it, have it done. I examine the urine of most patients, especially in subacute and chronic cases, no matter what the symptoms. Not to do so is to my mind as negligent as it would be not to look at the tongue, or feel the pulse, or ask about the appetite, or the character and frequency of the stools. Likewise should the eye be ever under suspicion.

But it must not be supposed that headaches due to eyestrain are located only at the eyebrows, as pictured in Butler's book on diagnosis. Eyestrain headache may exist in any part of the head. Nor is it noticeable, necessarily, at any particular time. The man who thinks it comes only after reading or in the latter part of the day, will overlook many cases, and some of them the most interesting, instructive, and thought-engendering. The practice of medicine is indeed a science as well as an art when one can reason back from effect to cause as unerringly as is possible in this class of patients. I have metaphorically gripped the malefactor in these obscure eyestrain cases after diligent search with as much gusto as Sherlock Holmes was ever portrayed by his creator as feeling when he caught his quarry, and with the same self-satisfaction for work well done and amply repaid.

Eyestrain may cause other than head pain. It may give rise to a diversity of symptoms, of which nausea is quite a common one. Then there is the head tilting due to un-

suspected peculiar monocular vision that persists until the spine is correspondingly twisted. Dr. Gould has said this, and has been laughed at for this one of his many keen analyses of eyestrain effects. Nausea may grow to emesis, this to malnutrition, and that to anemia and other ills that I confess myself reluctant to enumerate lest the little I have said be wholly discredited.

Mental irritability is quite a common accompaniment of eyestrain. So also, very naturally, is a disinclination to read, to study, to visit the theater, or to attend other public functions, for all may be a visual strain that causes unpleasant effects decidedly felt but not interpreted. Spectacles thus sometimes alter the habits of years. I have seen it, not once, but many times. What the ultimate effect of such relief may be upon the patient and those with whom he associates can be imagined, for even associations may be entirely changed.

It has often occurred to me that many men become therapeutic nihilists by seeing deep enough to realize that their drugging is on wrong lines, but not so deep as to see the simple cause of which the removal would result in prompt cure, even as Dr. Gould has cured a crooked back with the use of suitable spectacles. By the detection of eyestrain effects it is at times possible to achieve a well-merited reputation for acumen, sagacity, and good judgment. Pains, headaches, nausea, dyspepsia, irritability, insomnia, anorexia, mental sluggishness, and a host of other complaints have repeatedly yielded in my experience to suitable glasses after other efforts at relief by preceding consultants had failed. To all who doubt and are unable to make a proper examination of the eye, I would suggest sending persistent headache cases to an ophthalmologist for examination.

A. H. P. Leuf, M.D.

116 South Eighteenth Street, Philadelphia.

TREATMENT OF ACUTE SEPTIC PERFORATIVE PERITONITIS.

To the Editor of the Medical Record:

Sir:—In a communication to the Medical Record, January 12, 1907, Dr. A. E. Isaacs states that he is very much disturbed for fear that the readers of your journal will misjudge some of my conclusions in a recent article on Appendicitis, and that possible assistance through operative interference be denied some one. I take it that the members of the profession who peruse a valuable journal like the Medical Record are competent to decide whether statements are misjudged or not, and to this intelligent audience I am perfectly willing to trust the observations on appendicitis which have done so much to save life, and place the treatment of this disease upon a scientific surgical basis. The letter says "the conclusion regarding hopelessness and contraindication of operation in cases of general peritonitis are those generally accepted eight years ago. 'To operate—in every case, if there is a radial pulse, is up to date.'"

The truth is that the above statement is just the reverse of the facts, for it is well known that eight or ten years ago the dictum, I might say craze, was to operate in every case without regard to the period of the disease or the condition of the patient. Under this rule the mortality was so great and apparent, even to the laity, that its most ardent advocates were forced to modify their eagerness to "cut," which led to the more modern and scientific treatment of to-day. In support of this statement, it is only necessary to quote from the standard work of ten years ago, "Appendicitis," by Deaver, published in 1896, page 116, which reads: "Remove the appendix as soon as the diagnosis is made." A well-known and experienced surgeon says: "When a man proposes to operate on all cases of appendicitis, no matter what the condition of the patient, the extent of the disease, or its stages, provided only he can feel a pulse, he shows his lack of judgment and lack of ability to recognize the 'already dead' patient."

It is evident that Dr. Isaacs is ignoring the question of acute septic perforative peritonitis from the bursting of an appendical abscess, the subject I was discussing, and conveys to the profession an erroneous idea of the class of cases which I have called "inoperable." He says my descriptions are less definite, and would have us infer that there are no such cases with temperature of 105° or 106° and pulse of 140 or 160, etc. And yet with the next breath he says: "if permitted to last long enough, become general septic perforative peritonitis, with temperature of 105° or 106° and pulse of 140 or 160," etc. Everyone who reads these articles knows that general peritonitis, diffused peritonitis, purulent peritonitis, etc., as Dr. Isaacs describes them, means cases where nature is still holding the disease at bay; has her barriers up, as it were, and is still struggling to throw off the *materies morbi*, while in the condition I have described as acute septic perforative peritonitis from the bursting of the abscess, the sepsis is no longer limited. Nature is overwhelmed, annihilated, and capitulates in death, and these are the kind of cases in which I have said surgical interference is a "forlorn task." If Dr. Isaacs believes in operating in these cases, because "nothing is lost by operation," why not on this principle operate in all cases of tuberculosis of the lungs, all cases of advanced cancer of the stomach, etc., all along the line—as according to our author, "nothing is lost by operation" except the "surgeon's reputation." Besides, as Dr. Torey says: "Every failure tends to discourage surgery and discourage those who could and should be operated on with safety and benefit." I emphasize this because the wide publicity given Dr. Isaacs' statements by your journal "might result in the acceptance, here and there, of misjudged conclusions and consequent deprivation to many of the chances of possible assistance through operative interference."

Dr. Isaacs further writes at length, regarding the time of operation and the various pathological conditions of the appendix found when the abdomen is opened. There is nothing new in these cases, as we have all met with them, and they are, to a great extent, in the nature of surgical accidents similar to perforation of the stomach, intestines, gall-bladder, etc., either by ulceration or by perforation of foreign bodies. They are fully described in my former articles under the head of fulminating cases, and I need not take up the space to reiterate them here, but refer those interested to former reports. The cases of peritonitis Dr. Isaacs describes are like those reported by Dr. Murphy, except that in operating, Dr. Isaacs removed the appendix. These cases usually end in recovery with drainage, and the technique of removal of the appendix adds to the risk of the operation and is of no practical benefit, since the process that forms the abscess removes the portion of the appendix that is diseased, in the same manner that all morbid material is eliminated in diseased conditions where suppuration and evacuation take place.

In conclusion, let me hope that all my readers will observe carefully cases of death following operation for appendicitis, not only in their own, but in the practice of others. They will then see that the condition of the patient and the period of the disease must be taken into consideration, if we wish to give the patient with appendicitis the benefit of the wisest, most successful, conservative, and modern philosophical treatment. As one of the greatest authorities on appendicitis in this country writes, "It is only a question of time when all will be forced to accept this theory, as facts will overcome prejudice and tradition."

Dubuque, Ia.

OUR LONDON LETTER.

(From Our Special Correspondent.)

INFANTS' HEALTH SOCIETY—LONDON POOR LAW GUARDIANS—CARCINOMA IN MICE—AGGLUTINATION—BIER'S TREATMENT OF JOINTS—PANCREATIC DISEASE—ABSCESS OF LUNG—PARATHYROIDS—TETANY—DEATH OF DR. PEDDIE.

London, January 25, 1907.

The Infants' Health Society is opposed to the sterilization of milk, and last week a deputation from it was received by the President of the Local Government Board to urge, in view of his proposed bill, an investigation by a committee of experts. The Society was formed by laymen, but has a good deal of medical support. Sir T. Barlow said the deputation held that sterilization was only a "second best process" and might bring evils in its train. Once sterilized it was not possible to certify the purity of milk, and there were cases of immediate harm having resulted. Children fed on sterilized milk developed scurvy and rickets. As an alternative fresh milk should be cooled down immediately it was taken from the cow and kept cool in sterilized vessels. They therefore asked for an investigation on the methods of cooling. Sir Lauder Brunton followed, and strongly deprecated the enforcement of sterilization of milk, which in the long run was injurious. The addition of preservatives should be penalized. Mr. Burns, in reply, said there were only seven or eight sterilized milk depots in the country, and it was only just to extricate the local authorities from their apparently illegal position. The superiority of refrigeration had been put before him, but he did not think that the last word on the subject, and he did not see why local authorities should not be authorized to try either method.

Representatives of Metropolitan Boards of Guardians met last week to confer on the present methods of dealing with phthisical patients. Dr. Toogood said guardians had no power to alter conditions outside their own institutions. But as to patients in the infirmary their duty was to alleviate, or if possible cure, and, secondly, prevent a patient becoming a center of infection. Some boards were giving a modified open-air treatment, but that had its disadvantages. The number of cures would be small, for nearly all cases were far advanced before entrance. For the safety of other patients and of the officers, consumptives should not

be treated in ordinary wards. A separate block, with air space of 2,500 feet per bed, would be better. The said cases of patients and officers contracting the disease from those in the infirmary were frequent, and ought not to occur from a preventable disease, as phthisis was, if the community had the pluck to tackle the problem. Too much should not be expected from the open-air treatment; at the most, the disease would be checked, but it would infallibly resume activity on a return to the conditions of living which produced it. It was stated that the asylum's board has 2,000 beds at present empty, which it was recommended should be utilized for phthisical patients.

At the Pathological Society, Mr. F. W. Twort stated that in a stock of mice, not exceeding at any time 150, he had met a number of cases of cancer in the female breast; also two of the pylorus and one of the lung. The sarcosporidia of the mouse were found in the tissues around many of the tumors. The disease occurred in the older animals, and inoculation failed to propagate it.

Dr. T. J. Horder recorded a case of typhoid in which agglutination was absent. Diagnosis was made on the sixth day by growing the bacillus from the blood. Spots appeared on the eleventh day. Death occurred from heart failure. Sir A. E. Wright, president, suggested as explanation that agglutination is not a test of infection, but of immunity; if it failed in typhoid the prognosis was very bad, as it showed the patient was not immunizing himself.

Drs. Patch and Wells reported cases of tuberculosis of joints treated (Bier's method) by compression above. The opsonic index was found to rise, a fact they attributed to the passage of the exuded serum through the lesion taking back with it into the blood an amount of the toxic substance—a sort of auto-inoculation comparable to injection of tuberculin. Similar results followed massage or use of the diseased limb.

Pancreatic disease occupied the Medical Society on the 14th. Dr. Sidney P. Phillips remarked that an increasing number of cases of cancer of the pancreas might be explained by the decrease in cancer of the liver. It was said biliary calculi did not predispose to cancer of the pancreas, but his cases did not support this statement. The importance of fat and undigested muscular fibers in the tissues was recognized. Chronic interstitial pancreatitis, involving the head of the gland, simulated malignant disease. Jaundice without ascites indicated pancreatic rather than liver disease, though secondary nodules might appear in the liver before the end of the case. Cancer of the bile ducts also simulated pancreatic disease. Simple malignant disease of the head of the pancreas frequently could not be distinguished, even at the operation. Enlargement of the cervical glands, when present, was an important point. Glycosuria was rare in malignant cases. The so-called "salol test" was useless. He thought catarrhal jaundice was more frequently due to inflammatory swelling of the head of the pancreas than to duodenal catarrh. He thought drainage of the gall-bladder might be done prematurely, as many cases of catarrhal jaundice subsided after eight weeks.

Mr. Mayo Robson did not advise operation when a definite diagnosis of cancer of the head of the pancreas could be made. Some exception might be made when only the tail or body was involved.

Dr. Cammidge remarked that the reaction known by his name, although not pathognomonic by itself, would generally, in connection with clinical symptoms, enable a correct diagnosis to be made.

A case of abscess of the lung and acute endocarditis in acute pneumonia was related to the Clinical Society on the 14th by Dr. F. H. Hawkins, who remarked on the rarity of the complication, especially when, as in his case, the abscesses (there were three found in the inflamed lobe at the post mortem) had a distinct lining membrane. Dr. C. T. Williams said he had seen four similar cases of lung abscess, two influenzal. He had also seen abscesss and endocarditis in pneumonics. He did not think surgical interference offered a good prospect in such cases.

A paper was then read by Dr. David Forsyth on a fatal case of myxedema with changes in the parathyroid glands in a woman of fifty-eight, who had been developing the disease about four years before coming under observation. As the condition of the parathyroids found at the post mortem has not been previously described, the report naturally proved of interest. The six parathyroids found showed a marked tendency for the cells to form vesicles lined by cuhical epithelium, an exceptionally profuse secretion of colloid not only filling the follicles, but lying among the masses of cells and distending the lymphatic channels; an abnormal increase in the connective tissue, which formed coarse trabeculæ, and even penetrated between the cells; thickening of the arterial walls. The changes might perhaps indicate excessive activity of these bodies, to supplement the deficient colloid consequent on the atrophied thyroid, which presented the sclerotic changes usual in myxedema. The alterations in the stroma and arteries were probably pathological changes allied to those of the thyroid.

Mr. W. L. Harnett said he had examined many parathyroids, and considered the colloid as indicating increased activity; he could always correlate changes in the oxyphile cells with this, and asked their condition in this case. Dr. Walter Edmunds said experiment gave contradictory results, and our knowledge of the subject was very imperfect. Animals deprived of thyroid and parathyroids generally died, but a small percentage seemed to suffer no ill effects. In cases that recovered no traces were found of gland tissue which had been left. He thought work on the secretory nerves might yield information. He inquired if there had been any evidence of tuberculosis. In reply to these questions Dr. Forsyth said the oxyphile cells were scattered uniformly, and not in clumps, as in the normal. There was no active tuberculosis, but a calcified focus was found at one apex. Experiments had shown no effects following section of the secretory nerves.

Dr. F. Langmead then read notes of three cases of tetany associated with dilatation of the large intestine in children (ages 6, 3, and 2½), and which he thought formed a tolerably definite but unrecognized group, to which four attributes were common, viz., (1) obstinate relapsing tetany; (2) abdominal distention; (3) offensive unhealthy motions; (4) dilated large intestine. In all the cases the tetany disappeared after the bowel was irrigated, but it returned when accumulation of the feces was allowed. This, Dr. Langmead thought, showed toxic absorption to be the cause, and so far favored the toxemic theory of tetanus in general. Malnutrition, prominent in these, as well as previously recorded cases, seems to point to undue irritability of the nervous system. Some remarks were made by Drs. Turney and Garrod as to the possibility of distinguishing dilatations of the sigmoid and the colon. The president, Mr. Clutton, said he had operated on two cases in adults. He favored preliminary drainage of the colon for about a month before attempting resection.

Dr. Alexander Peddie of Edinburgh died on the 19th inst. at the great age of 97. He took his M.D. and L.R.C.S., Edin., in 1835, and was reckoned the oldest doctor in Scotland, perhaps in the United Kingdom. He had filled various posts in his time, including the presidency of the Royal College of Physicians, Edinburgh, and was F.R.S. and member of various other societies. His recollections of Dr. John Brown, the author of "Rab and His Friends," were a constant source of pleasure to the literary coteries of "Auld Reekie," and some were embodied in his Edinburgh Harveian Oration (1890). He wrote also an account of Brown's life and work, and contributed papers to the medical societies and journals. Of course, he has been retired for some years, but Edinburgh will miss him still more than during the time the veteran was still among her living notabilities.

OUR PARIS LETTER.

(From Our Special Correspondent.)

SPONTANEOUS GENERATION—ELECTRIC SLEEP—TREATMENT BY CATAPHORESIS—THE TREATMENT OF VARICOSE VEINS—ALOPECIA AREATA—SPLENECTOMY FOR INJURY OF THE SPLEEN—URETEROVAGINAL FISTULA.

PARIS, December 28, 1906.

A SERIES of very interesting lectures on the origin of life in general have just been held in Paris by Professor Leduc of the University of Nantes. The important studies that he has made, and the curious results obtained again bring forward the question of spontaneous generation, for his experiments seem to indicate the possibility of a transition from the mineral kingdom to the vegetable. By a chemical process that he has devised he appears actually to create artificial plants. This is the method: To make a seed he takes two parts of saccharose and one of sulphate of copper, which he pulverizes and mixes. He takes a pinch of this powder and with a drop of water makes it into a little granule. Then he prepares a culture medium composed of water, ferrocyanide of potassium (2 to 4 per cent.), chloride of sodium (1 to 10 per cent.), and gelatin (2 to 4 per cent.). He puts a small amount of this medium in a test tube and drops into it the artificial seed: in a few minutes this seed begins to swell, elongates and finally forms a sort of stem, and later on several trunks and branches, which, in a few hours may reach a length of twenty-five to thirty centimeters if the dimensions of the tube permit it. The structure so obtained has the appearance of an aquatic plant, and presents the semblance of roots, stems, of structures that to some extent resemble leaves, and enlargements which suggest fruit. The stems on reaching the surface of the liquid spread out like floating leaves. If, in place of using a tube, the experiment is performed in a wider and deeper vessel, the cultures have a different appearance, and resemble algæ or sometimes

moulds. This curious product of growth which resembles a plant may have several hundred times the bulk of the original granule, and the material necessary for this increase in size is obtained from the culture medium, that is, there must be growth by absorption. The structure is a complicated one, since in addition to the differentiation of horizontal roots, vertical stems, leaves, and terminal organs there must exist some special mechanism by means of which the membranogenous substance and sugar can acquire a length up to thirty centimeters. These three functions, nutrition by absorption, growth, and differentiation, which so far have been considered characteristic of life, are, therefore, reproduced by purely physical forces. The growth of these artificial cells is very susceptible to physical and chemical stimuli, they cicatrize their wounds, and, when a stem is broken before its development is complete, the fragments reunite and growth recommences. Only a single function is still lacking to the synthesis of life—the faculty of reproduction.

These interesting experiments were made by Professor Leduc in the lecture room of the Societe de Chirurgie de Paris, and the same speaker also presented two other important discoveries. By a special method he has succeeded in producing electric currents of a hitherto unknown form by means of which it is possible to cause artificial sleep. Leduc first subjected himself to the action of the current and made careful notes of the sensations experienced. He found that although consciousness persisted during a long period, the subject undergoing the electric sleep was entirely unable to give any evidence of his conscious state by movement or other means. The graduation of the current can be effected slowly and systematically, but if carried too far death may be occasioned. As Professor Leduc points out, in order to do this comparatively weak currents are sufficient, which is in contravention to the custom in countries, such as America, where, for the execution of criminals, extremely strong currents are used.

Finally, Professor Leduc has also perfected a method of electric medication. It is well known that the electric current decomposes chemical compounds, and that it may be used to cause remedial agents to penetrate into the living tissues. When a current is passed into a solution that is not a nonconductor the acid radicals are always set free at the positive pole, while the metals and bases are set free at the negative pole. By employing this principle Leduc causes active substances to penetrate the tissues, and he has especially studied sodium salicylate, which is of value in the treatment of tic douloureux, and also iodide of potassium. In the latter case the solution is placed at the negative pole. Sulphate of quinine is used with the positive pole as is also chloride of zinc, which has been found to be a powerful hemostatic and antiseptic.

A new method for treating varicose veins of the leg was described by Dr. Pierre Delbet before the Academie de Médecine. It is generally considered that the production of varicose veins is principally due to the insufficiency of the venous valves, and attempts have been made to overcome this deficiency by ligature and by resection of portions of the interior saphenous veins. These methods have not proved satisfactory, however, and Delbet proposes to remedy the condition by a new operation which consists in anastomosing the saphenous vein with the femoral vein, which latter is well provided with valves. The juncture is effected in the middle third of the femoral vein, and is said to have given excellent results.

At the Conseil d'Hygiène the conclusions of Dr. Duguet concerning alopecia areata were officially adopted. This observer founding his conclusions on the experiments and studies of Sabouraud and Jacquet, advocated the adoption of the theory of the noncontagiousness of this form of baldness. Formerly, children suffering from alopecia were kept out of the Parisian schools, but in Duguet's opinion this is not necessary, and there is much experimental evidence to sustain his view. The parasitic theory of the disease has been abandoned by most observers, and the condition is generally considered to be one of trophoneurotic origin.

An unusual case of injury of the spleen treated by splenectomy and followed by cure was reported to the Société de Chirurgie by Dr. Barnsby of Tours. The patient was a butcher, aged twenty-eight years, who was stabbed with a knife in the eighth intercostal space in the left side. Six hours later he manifested signs of extreme internal hemorrhage, with pain and muscular rigidity in the left flank. The operation was done nine hours after the injury. By means of a transverse incision parallel with the costal border the peritoneum was opened and found full of blood, the spleen was so severely injured that a fragment representing about one-quarter of the organ was almost completely detached. Splenectomy was performed, and the patient recovered.

Another interesting case was reported by Dr. Jeanbrau of Montpellier. The patient was a woman of twenty-one years who, as the result of pelvic peritonitis had been subjected to a posterior colpotomy by means of which an abscess cavity had been drained. Four days later she noticed that urine was voided through the vagina. Jeanbrau, after having first made use of the segregator of Luys, discovered that there was a fistula communicating with the left ureter, and some time later, by means of the direct vision cystoscope of Luys, he succeeded in introducing a catheter into the injured ureter. Eight days later the catheter was removed, and since that time no leakage has taken place. Jeanbrau stated that a search of the literature had failed to reveal any case of ureteral fistula following pelvic peritonitis similar to this.

OUR LETTER FROM COPENHAGEN.

(From Our Special Correspondent.)

NOMA—LIGHT TREATMENT IN AFFECTIONS OF THE MUCOUS MEMBRANES—LIGHT BATHS IN ANGINA PECTORIS—NEW HOSPITAL BUILDINGS.

COPENHAGEN, January 25, 1907.

THE etiology of noma has frequently been studied, but as yet the question cannot be regarded as settled. It may, therefore, be of some interest to draw the attention to a research regarding this point by Dr. E. Hellesen of Christiania. The case of noma examined by our Norwegian confrère was in so far somewhat unusual, as it occurred in a child that had been in entirely good health until it began to suffer from noma. Dr. Hellesen found in this case a well-defined diplococcus, which he believed caused the affection. He was led to this conviction by the following circumstances. In the first place he found the microbe in question to be constantly present in all preparations from the diseased tissues. Secondly, having succeeded in isolating the diplococcus, he was able to produce a typical necrosis of the skin and adjacent tissues by inoculation of the pure culture in rabbits, just as when particles of the original noma were used for inoculation. As far as regards this one case, the question of the etiology must be said to have been solved. But the author is cautious enough to admit the possibility of several microbes being able to occasion the clinical picture of noma.

In the Copenhagen Medical Society, Dr. K. K. K. Lundsgaard read a paper on light treatment of affections of the mucous membranes. He had treated seven cases of lupus and two of primary tuberculosis of the conjunctiva with very good results. The difficulty that the light treatment of such diseases had hitherto encountered was that the light could not be made to act directly on all points of the affected mucous membrane. But Dr. Lundsgaard had now been able to do this by using the complete reflection of the light rays in prisms with the angles 90°, 60°, and 30°. The sides of the prisms were formed by plates of rock crystal with plane and parallel surfaces, the prism being kept cool by cold water running through its interior. The prism was inserted between the bulbous center and the eyelid, and the light rays directed perpendicularly against the free surface of the prism, so that it was completely reflected from the hypothenuse and passed out into the tissues through the surface opposite to the angle of 60°. In order to secure a total reflection, it was essential to avoid the moistening of the reflecting surface, wherefore the latter was covered with an air-tight metal cap, and the space between the reflecting surface and the metal cap filled with thoroughly dry air. When using this kind of prisms the only drawback was that this air in the course of the treatment absorbed some moisture from the tissues against which the prism was pressed, so that it was necessary from time to time to replace the moist air by a fresh supply of dry air. Experiments (with promising results) had also been made with prisms of less complicated structure. As investigations had shown that a mirror made of amalgam of mercury on a rock crystal plate only absorbed about 30 per cent of the chemical rays, the unprotected hypothenuses of the above mentioned prisms were in other prisms replaced by such a mirror. The cases treated with these less complicated prisms had shown satisfactory progress.

At the same meeting the director of the Finsen Light Institute, Dr. H. Forchhammer, [illegible] very promising results in upwards of one hundred cases of lupus of the upper respiratory tract treated in the institute by Dr. Lundgaard's prisms. The best results were seen in affections of the anterior part of the nasal cavity (good results in 38 out of 47 treated cases), in affections of the mucous membrane of the interior surface of the cheeks and in affections of the tongue. Here he especially mentioned a case of lupus of the tongue which formerly had been treated for years by other methods, but had very

been cured in a relatively short space of time. He sought the explanation of the good results in the fact that it had now become possible to realize the conditions of an efficient light treatment, laid down by Finsen, viz., that the light rays were directed perpendicularly against the diseased tissues, which at the same time were kept cool and anemic by the pressure of the water-cooled prism.

Some months ago I mentioned Dr. Hasselbalch's work in connection with the Finsen light baths. At a meeting of the Copenhagen Medical Society, Dr. H. Jacobous read a paper on angina pectoris, and said that of fifteen cases he had seen fourteen improved or cured by the light baths. He explained the efficiency of this treatment by the dilatation of the cutaneous vessels and the accompanying decrease in the arterial pressure, whereby the work of the heart became less taxing. An animated discussion arose on this point. Prof. Chr. Gram said that the cases were too few in number, and the time of observation too short, to allow of definite conclusions; besides, one often saw improvement by other methods of treatment, as well as long periods free from attacks; also, it was difficult to exclude the effect of suggestion. As an apt illustration of the last, Prof. Israel Rosenthal communicated the observation of a patient who had the sensation of a pronounced improvement, but in whom nevertheless the disease made rapid progress after every light bath. Prof. Friedenreich drew attention to the difficulty of prognosis. A patient of his, whom he had sentenced to death, lived for fifteen or twenty years. Prof. Henriques thought the theoretical foundation of the treatment to be of little value. The decrease of the arterial pressure in the brachial artery, found by Dr. Hasselbalch in his investigations into the effects of the light baths, was in itself very small, and not equivalent to a decrease of the aortic pressure, which latter only was of importance. But even if the light baths caused a decrease of the aortic pressure, the treatment might be harmful in many cases, for example in hypertrophy of the heart muscle in connection with kidney diseases. Prof. Johs. Bock also thought the theoretical basis of the treatment weak. Dr. Hasselbalch, who was present at the meeting, did not speak.

In our largest and most up-to-date hospital, the Kommunehospital, which harbors upwards of 1,000 patients, a new and beautiful building has just been opened as a home for the nurses in the hospital service. The house shelters 126 nurses and has cost $80,000 to erect.

Progress of Medical Science.

New York Medical Journal, February 2, 1907.

Age Limitation of Sports.—H. Toeppen makes a plea for the continuation of gymnastic and athletic sports beyond the age at which they are usually given up. He declares that as to the hardening of tissues, rigidity of arteries, etc., as a consequence of age, there is no rule of general applicability. Naturally if arteries are left undisturbed and are just expected to keep up a sluggish circulation sufficient to supply the wants of a more or less (bodily) lazy business man, they will assume considerable rigidity about the fortieth year; but if they are made to respond to sudden and energetic calls for increased and lively circulation (without frequent excessive demands and these calls on them are made daily) they will last a good deal longer in consequence of improved nutrition of their walls and a more lively excretion of waste and stagnation products. He then goes on to apply the foregoing principles to such common sports as running, skating, and to gymnastic work, concerning which he says there is no limit for anyone and no excuse for its omission. Only, he says, we must individualize with reference to each particular patient. Some very sensible and practical rules are given.

The Surgical Application of Blood Examinations.—This subject is considered by J. B. Deaver, who considers the findings with reference to the red cells in acute post-hemorrhagic anemia and symptomatic anemia. He is not inclined to attach much value to the findings in the first because the surgeon's immediate task is to stop the bleeding, whereas the histological changes in the red cells in such conditions are not found until the end of twenty-four hours. As to the findings in cases with small but frequent hemorrhages in connection with chronic suppurative processes or tumors, a hemoglobin percentage below twenty-five, a paucity of small distorted red cells, and a disease-spoiled body, the author thinks that the condition calls for the most serious contemplation before any operation is undertaken. Concerning the white cells, he declares that the familiar count cannot always be relied on. Leucocytosis is usually found, however, in infections leading to suppuration in any part of the body. It is to be looked upon in general as a measure of bodily resistance. He does not find the count of much value in acute pyosalpinx, except in differentiating from uterine fibroids, ovarian cysts, etc., and one should constantly bear in mind that these may give a leucocytosis when suppurating. The average hemoglobin index is much lower in tubal disease than in appendicitis, and the finding of only fifty or fifty-five per cent. of hemoglobin and a moderate leucocytosis corroborates strongly in making a diagnosis when the clinical signs point to a pelvic collection. The differential count is of value if carefully performed with properly stained films and a count of at least 500 cells. Theoretically, it should always be made, but it is not always possible. He accepts the general conclusions of Sondern on this point, and adds that in lead colic a differential count would be of great value, as the basophilic granulation of the red cells would at once attract attention and decide the diagnosis. But one should remember that lead workers may get appendicitis, and that a leucocytosis is sometimes encountered during the acute stage of plumbism.

Common Misconceptions in the Pathological Physiology of the Circulation and Their Significance.—T. C. Janeway refers in this interesting paper to the great value of the observation of blood pressure in such diseases as typhoid fever, pneumonia, nephritis, etc. In many cases of these diseases the danger lurks not so much in the heart itself as in the vasomotor apparatus. Much of the drugging which is done in the crises of these diseases is utterly useless and even harmful. Effects produced by various valuable therapeutic measures, such as the tub in typhoid, are of value just in proportion as they bring the blood pressure up to normal. Concerning abnormally high pressure, he says that it is found independently of chronic Bright's in at least ten per cent. of all cases. Its causation in these cases is unknown. It has been suggested that the anatomical changes in heart and vessels are secondary to the increased blood pressure, as most of us have believed, though a few have dissented; secondly, that the hypertension is due to widespread vasoconstriction, of toxic origin, from retained metabolic products. That a general increase in vasomotor tone is responsible for the hypertension agrees well with the facts of clinical observation. Heightened blood pressure may be a necessity in many cases of Bright's in which secondary arteriosclerotic changes have taken place in the smaller vessels, which add a permanent element of increased resistance; hence the futility, to say no more, of attempting to keep down the pressure in such cases. In the presence of peril, however, such as uremia, angina, hemorrhage, etc., the vasodilators should be used freely. In the ordinary case with edema and diminished urine excretion, the freshly made infusion from good English leaves is urgently indicated. Rest in bed should be insisted on and the fluid ingested limited. Under these circumstances a rise in blood pressure is to be looked on as a good sign and usually coincides with the establishment of diuresis and relief of the dropsy.

Journal of the American Medical Association, February 9, 1907.

Experimental Chronic Nephritis.—W. Ophuls considers that the textbooks may convey a somewhat insufficient idea of the amount and value of the work that has been done in the study of experimental chronic nephritis. He refers to Ehrlich's and Levaditi's experiments with vinylemin as showing that if time enough is given in the experiments, the lesions of chronic Bright's disease are likely to be developed, and also to those of Heinecke and Passler as likewise instructive in this regard. He reviews the literature of the experimental production of chronic nephritis by poisons that directly affect the renal cortex and are reported to cause interstitial changes, such as aloin, boracic acid, cantharidin, potassium chlorate, chromic acid and the chromates, lead and other heavy metals, oxalic acid and oxamid, sulphuric acid, and various bacterial toxins. He also gives an account of his own experiments. He first employed lead, because it is the only substance that we know with certainty to produce chronic nephritis in man. Of course, the smallest possible doses had to be employed to reproduce a disease of such chronicity, but even then the lead anemia produced was the greatest obstacle to the experiments being carried out for a sufficient length of time. In all cases the lead was administered by the mouth, as this comes closest to the natural conditions, in guinea-pigs, to which from 1.5 to 3 grams of carbonate of lead had been given in the course of from two to five months; only the incipient stages of chronic nephritis were found, but in one dying about four months after the discontinuance of the administration,

more advanced lesions were observable. The same incipient lesions as in the guinea-pigs—necrosis and desquamation of epithelial cells of the convoluted tubules and ascending loops of Henle, cellular infiltration around the blood-vessels near the glomerules—were observed in one dog that had taken only 0.8 gram of lead acetate in six weeks. In other dogs that had taken larger amounts given over longer periods a marked chronic interstitial nephritis was manifest. In spite of careful and repeated examinations, neither albumin nor casts were found in the urine, which gives support to the suspicion that similar conditions may exist in man without such evidence. In order to supplement the experiments with lead, two dogs were given small doses of bichromate of potassium in milk. One of these was lost in the confusion following the earthquake, but the autopsy of the other, which had received nearly 11 grams of the bichromate during the course of four and one-half months, showed more pronounced lesions than those dogs that had been dosed with lead and under observation for a year or more. The bichromate, therefore, seems to promise well for future experimentation along these lines. Ophüls proposes to continue the research with hope of obtaining more definite disturbances in circulation with consecutive cardiac hypertrophy, and of obtaining some information about the relation of renal and vascular disease in chronic nephritis.

Rheumatism in Children.—J. Ross Snyder questions the present tendency to widen the conception of rheumatism in childhood. He says that, eliminating scurvy, pyemic arthritis, and the soreness and stiffness of muscles and joints from clothing, coddlings, and bouncings, the cases of rheumatism in nurslings are almost nil, and from the eighth year onward an attack of rheumatism in a child resembles more or less closely the adult type. He gives a list of a number of conditions that have been regarded as occasional manifestations of rheumatism, and some of these have in certain cases a connection that cannot be denied. The most important of these are the cardiopathies, especially endocarditis, but in view of the number of infective processes that are capable of causing both arthritis and endocarditis, Snyder thinks preconceived notions as to the association of the two disorders will cause many mistakes in diagnosis. As regards chorea, tonsillitis, and erythema nodosum, he is inclined to think the evidence as yet insufficient to prove their relations to rheumatism. As regards the many other conditions considered to be manifestations of child rheumatism, his opinion is that they will "one by one be taken away from this connection until rheumatism will come to mean, not everything, but something or nothing."

Rheumatic Fever in Childhood.—C. H. Dunn concludes that at present it seems advisable to accept the *Micrococcus rheumaticus* of the English investigators, Poynton and Paine, not as the absolutely proven, but as the probable cause of this disorder. A careful study of some three hundred cases treated at the Children's Hospital, Boston, during five years, brings out the following points as characteristic of the disease, as here conceived, in early life: (1) The comparative mildness of the articular manifestations. (2) The relative frequency of cardiac manifestations. (3) The large number of cases in which only cardiac manifestations occurred; an actually greater number than those with only articular symptoms. (4) The frequent primary occurrence of endocarditis or pericarditis. (5) Cardiac manifestations are the most severe. In acute endocarditis, and even more in acute pericarditis, the severity of the case and danger to life are greater than in acute arthritis. (6) A notable feature was the tendency to recurrent attacks with varying manifestations, arthritic, pericardial, etc., and not following any particular order, one form one year and another form for another year. What is called "broken compensation," and generally attributed to overexertion, was observed in 121 of the 300 cases. Dunn attributes it here to a fresh infection rather than to overstrain. As regards diagnosis, he says, given any case of arthritis, especially if with the physical signs of endocarditis, or any case of acute infectious disease without other localization than in the pericardium or endocardium in childhood, the probability is that it is a case of rheumatic fever. Previous attacks, chorea, sore throat, etc., strongly increase this probability. Endocarditis, and other infections from the pyogenic cocci or as complications of other recognized infections are readily diagnosable. As regards prognosis, he says, many physicians do not recognize that the chances of death may be as high as one in five. The cardiac complications are more frequent than in the adult. The severest form is pericarditis, with a high mortality. In conclusion, Dunn points out that the general characteristics are those of a definite clinical entity, and most probably a specific infection to be placed in the same rank as scarlet fever and measles as definite disease species.

Autointoxication in Relation to the Eye.—G. E. de Schweinitz discusses the question of autointoxication, more especially that from the gastrointestinal tract, in relation to the eye. He finds that a number of morbid ocular conditions, including optic neuritis and retinitis, ocular muscle anomalies, affections of the cornea and sclera, and disease of the uvea, may possibly or probably be referred to this cause, and points out the importance of accurate and thorough urine investigation by the latest clinical methods of diagnosis in these cases. He summarizes as follows: "Although we do not know the entity of a single autointoxication, except the acidosis of diabetic coma, and although we know that no known autointoxication is to be attributed to any known end product of any known metabolism, to quote Alonzo Taylor, we do know, from clinical analogy at least, that 'autointoxications exist, even if their true nature is as yet a secret.' We do know, too, that after food is swallowed and before the end-products of assimilation are eliminated there may be processes arising under abnormal conditions which yield poisonous products foreign to normal metabolism, the reabsorption of which may be followed by definite symptoms. We have reason to believe, in the absence of other causes, that ocular troubles may also arise largely in the corneoscleral and uveal tracts, and probably in so far as the nervous apparatus is concerned, in manifestations to which we apply the term acute or chronic retrobulbar neuritis. We do not know whether these toxins, whatever they may be, actually are the only and sole cause of these conditions, but such examinations as have been made by Elschnig, by Kraus, by Grayer, by Edsall, and by myself at least indicate that, to use Elschnig's term, they may be considered accessory causes. As Edsall and I have said, they may be able to play a certain part in the production of the symptoms, and at times are probably the direct cause of their continuance, even when other more commonly accepted etiological factors have ceased to be active."

The Lancet, January 26, 1907.

Glandular Extract from Immunized Animals as a Curative Agent in Plague.—S. Mallannah reports the results of experiments in fifty rats and guinea pigs. Healthy rabbits were inoculated with Haffkine's prophylactic fluid in sufficient degree to give them a slight immunity. Later they were inoculated with the plague bacillus and then while still quite sound chloroformed. Microscopic examination of the juice of glands of such animals did not reveal the presence of any bacteria and no growth was obtained on the media inoculated. The details of preparing the glandular juices are given in full. He was led to these experiments from consideration of the well known clinical fact that the cases of the plague which recover are those in which the glandular reaction is most marked, while the most serious cases are those in which the glandular reaction is hardly observable. It is also noted in the laboratory that marked pathological changes are found in the lymphatic glands, spleen, and liver, especially in those animals in which for some unknown reason the disease runs a chronic course.

A New Sugar Test.—H. J. H. Fenton describes this test which is delicate enough to detect one-tenth per cent. sugar in urine and other body fluids, or even less. The reaction depends on the fact that all carbohydrates of the hexose, or polyhexose, type (such as dextrose, levulose, cane sugar, milk sugar, or maltose) yield a certain amount of bromomethylfurfural, $CH_2Br—C_4H_2O—CHO$, when acted upon by hydrobromic acid under appropriate conditions; and further, that the latter substance reacts with malonic ester in presence of alkalies, giving rise to a product the solutions of which exhibit a powerful blue fluorescence. The conditions most favorable for the action of hydrobromic acid are obtained when phosphorus tribromide is dissolved in some inert solvent, such as toluene, and the solution is heated with the carbohydrate in presence of water; excess of water, however, must be avoided. For the examination of urine the test is most conveniently applied in the following way: Pour a small quantity (four or five cubic centimeters) of the liquid on to an excess of solid anhydrous calcium chloride so as to form a semisolid, or pasty, mass. Add to this ten cubic centimeters of toluene containing two or three drops of phosphorus tribromide and then carefully boil the mixture for a few min-

utes, bearing in mind the inflammable nature of toluene. Pour off the toluene solution and, after cooling, add to it about one cubic centimeter of malonic ester and a little alcohol. On neutralizing the mixture by adding alcoholic potash, drop by drop, a characteristic pink color will usually be observed. The mixture is now considerably diluted with alcohol and a few drops of water when, if sugar was originally present, the solution will exhibit a beautiful blue fluorescence. The reaction appears to be a specific one for carbohydrates which contain six or more atoms of carbon in the molecule and may therefore be used to distinguish hexoses from pentoses or other lower sugars.

Observations on the Induction of Autovaccination in Tuberculosis and other Chronic Glandular Infections by the X-Rays.—These observations are recorded by H. D. McCullough, who bases his work on the revelations of the opsonic chart in the tuberculous cases. Their purpose is to demonstrate the theory that the mechanism of the therapeutics of the *x*-rays rests upon the induction of an autovaccination, subsequent to the resolvent action of the rays on the rudimentary neoplastic encapsulating tissues about the tuberculous glands, thus rendering the vaccine accessible to the blood-vessels. It is also shown in the paper how the effects may be observed by minute temperature reactions, accompanied by similar advances in the opsonic index without negative phases, tested by the periodic estimation of the opsonic index to the tubercle bacillus. The author refers to the admitted fact that all neoplastic tissue is a rudimentary replica, almost in every detail, of the tissue affected and that such tissues are highly susceptible to the influence of the *x*-rays and of the less penetrating cathode rays. These stop short of damage to the normal and more organized tissues when they are judiciously applied, and they restore metabolism when it has more or less come to a standstill. The author states that he is tempted by the obvious therapeutic parallelism in the recently reputed medicinal agents in cancer to enter into their probable therapeutic values as recorded in the experience of others. He refers to papain, trypsin, and amylopsin, but adds that these enzymes, when injected in emulsion into the encapsulating tissues where metabolism has come to a standstill, bring about active resolution (if veins are avoided) by virtue of their proteolytic and diastatic properties on those tissues, when the lesions are accessible and not too deeply situated. They may thus liberate the vaccine when present in the lymphatic glands with the desired result if they do not influence it unfavorably by admixture before neutralization.

X-Ray in the Treatment of Carcinoma and Sarcoma.—C. Williams notes that all the theories advanced to account for the influences of the rays on malignant growths seem to point to a leucocytosis being ultimately produced in or around the growths. According to one authority, they have a special selective action on new growths, the cell nuclei swell, do not stain well, the outlines of the cells become indistinct and fuse, the protoplasm becomes granular, is invaded by leucocytes and absorbed, leaving a network of dense connective tissue containing vessels with thickened walls from endo- and periarteritis caused by the rays. Some sort of reaction seems to the author absolutely necessary. This reaction may take the visible form of redness in the mass if protruding through the skin or round the edges of an ulcer, swelling or hardness of the tumor, increased heat, perhaps in some cases increased pain or other vague undefined feelings to the patients. If a discharge be present it soon takes on a more healthy nature, both as regards appearance and odor. Sometimes there is pent-up pus, with elevation of temperature and night sweats. The rays should be used both before and after surgical intervention. Failure may result from inexperience of the operator, weakness of the apparatus, too weak or too energetic treatment, the hopelessness of the case, dissemination of the disease throughout the internal organs, or the patient's low vitality. Except in cases in which the growth is extremely small, the author thinks it best not to screen the surrounding tissues. The pain of malignancy can be greatly alleviated by this mode of treatment. The pain that one sometimes notices in cases where it is obviously due to the dragging or contraction of the scar does not seem to yield so readily as "growth" pain. Pain produced by pent-up discharge or the disintegration and liquefaction of the malignant cells can only be relieved by the patient's disruptive powers or by an exit naturally or artificially produced. In uterine cases it is important carefully to distinguish between the period pain and the pain of the growth while under treatment.

British Medical Journal, January 26, 1907.

Urethral Abscess and Calculi.—F. G. Hack reports the case of a man of thirty-four years who was operated on for perineal abscess. A quantity of pus was evacuated and the presence of a large calculus revealed. This was extracted with lithotomy forceps, and afterwards found to weigh over one-half ounce. A sound passed into the bladder detected no calculi, nor could any communication between the bladder or urethra and the cavity containing the calculus be discovered, but subsequent to the operation a small quantity of urine escaped from the perineal opening during micturition. When seven years of age the patient had undergone an operation for stone, apparently by lateral lithotomy, the perineal abscess occupying the site of the old scar.

Incubation of Scarlet Fever.—Commenting on the fact that most text-books give the incubation period in this disease as from one to seven days with an average of from two to four days, E. L. Jenkins states that it is often much longer. From an extensive hospital experience he believes that it is often to three or four weeks. Owing, he says, to inevitable errors in diagnosis, a certain number of cases are sent in as scarlet fever which are not so. A child, for instance, suffering from sore throat, with a pseudo-rash, and the concomitant signs and symptoms of some fever being present, the case is diagnosed as one of scarlet fever, is consequently notified as such, and is immediately sent for isolation. On the following day, however, the little patient is found, to all intents and purposes, quite well, with an absence of fever and no trace of any rash. This change within twenty-four hours is very marked, while the general appearance of the patient during the next few days will serve to prove that an error of diagnosis has been committed. This being so, we cannot even place such a case among the category of the "simplex" or mildest form of scarlet fever. Nevertheless, owing to the absence of an observation ward in the author's hospital such a child is placed among the genuine cases of scarlet fever, and is from the moment of admission open to infection, and yet cannot be discharged just then. Under such favorable conditions for infection he finds that such a child does not contract the disease within seven days—the limit incubation period as generally given—but on the other hand shows unmistakable signs of infection in from three to four weeks after admission to the scarlet fever wards. The type of fever in these cases is somewhat severe, the signs and symptoms being usually typical of those varieties of scarlet fever recognized as "scarlatina anginosa" and "scarlatina maligna."

Treatment of Myoma of the Uterus.—J. F. Jordan believes that uterine fibroids call for active treatment and that it is wrong to allow the condition to go unrelieved, providing of course that symptoms are present. Most frequently we find hemorrhage and, nearly as often, pain due largely to a complicating inflammation of the appendages with adhesions. Cases die more often than is realized from the effects of repeated hemorrhages and consequent debility. It is not true that fibroids "do not kill." The mortality of hysterectomy is not great, certainly not over five per cent. Myomectomy may be done if the patient is under forty years, if pregnancy coexists, if a tube and ovary capable of functionating can be preserved, and if it can be done so as to leave a uterus practically sound. Recurrence must be admitted as a possibility. Minor measures, as curetting and electrical treatment, are absolutely useless. As to oöphorectomy it is not to be compared with hysterectomy as a routine procedure for the following reasons: (1) The operation of oophorectomy is attended by quite as large, if not a larger, mortality than hysterectomy. (2) It is quite as difficult an operation to perform, and takes very nearly as long. (3) The immediate post-operative condition is much more distressing, there being much more pain after oophorectomy than after hysterectomy. (4) The general convalescence is longer and much less easy. (5) The ultimate cure cannot, on the face of it, be as certain. If we perform a hysterectomy we remove the stretching on the broad ligaments caused by the fibroid. In the Trendelenburg position, with all the bowels and omentum tucked up in the abdomen away from the pelvis, one can fashion the peritoneal flaps, tie the vessels so that the stumps drop under, and can be easily buried under the peritoneum. The author never sutures the cervix. He simply brings the anterior and posterior flaps of peritoneum together with a continuous fine silk suture. At the end of the operation one can look down into the pelvis, and there is between the bladder in front and the rectum behind nothing but the line of suture visible, lying in the pelvic floor with no strain whatever upon it. If the appendages are not diseased he does not remove them.

The Cause of Acute Illness Supervening During Menstruation.—A series of cases is summarized by T. Holmes. He refers particularly to three instances in which an apparently normal menstruation is interrupted by signs of a sudden pelvic inflammation. Under such cir-

cumstances he has several times found small but very sensitive ovaries. There may also be accumulation of blood hematocele. Such cases undoubtedly start as hemorrhage from a Graafian follicle, engorged with blood as it is, at the menstrual epoch, the exciting factor being undue exertion, causing intraabdominal pressure. In another case of the author—recovery from acute lobar pneumonia—menstruation came on and the patient was seized with acute pain in the left iliac fossa, together with nausea and vomiting. Examination showed a prolapsed, enlarged, and very tender ovary. In such a case one must consider the possibility of blood infection by the pneumococcus as either attacking a healthy ovary and setting up an ovaritis, or attacking an ovary in the substance of which blood has been effused, owing to the rupture of an engorged Graafian follicle, causing an infection of it, and so setting up an inflammation. In still other cases the pelvic inflammation may result from septic conditions in either rectum or vagina, or both. The clinical history of one case in this category closes the author's paper.

The Food Factor of the Twentieth Century.—G. J. Sealy calls attention to the increased amount of bowel disease of the present day. He attributes it largely to the increased consumption of meat. Those who eat the most meat are those who want the most meals. The stimulating property of meat is largely responsible for the fact that those who have for a time abandoned the use of meat at breakfast and lunch, and who confine their indulgence in it to once a day, find that what they were disposed to regard as a mere apology for a meal sustains them better and for a longer time than what they wrongly thought was the more substantial and valuable material. Cookery, in England, says the author, has altered to the extent that solid foods are made mechanically more digestible, not an unmixed gain, as excesses are simplified, and indiscreet indulgers are not warned by the epigastric storm-signals which formerly brought them to account. Some years ago the author restricted his proteid intake to one-third of his former allowance, and found himself greatly benefited in every way. Proteid restriction has a most beneficial effect on the peripheral circulation, in the sense of a feeling of increased warmth and general well-being. Much of the so-called "nervousness" of the present day is merely the result of autointoxication from too great proteid indulgence. A large amount of energy is used up in passing on nitrogenous waste products from organ to organ, or from tissue to tissue, on the way to elimination, and that liver and kidneys ultimately rebel at the excessive labor is not to be wondered at, and when the products that result from the breaking down of nitrogenous waste fail to go through the processes in the hepatic cells and elsewhere that Nature intended, very serious symptoms inevitably result.

Berliner klinische Wochenschrift, January 21, 1907.

The Flotation Test of Infants' Lungs.—Marx states that it is two hundred and twenty-five years since Johann Schreyer first made forensic use of the floating test as a method of determining whether the lungs of a newly born child had ever been distended with air or not, and the performance of this test is still one of the duties of the pathologist making an autopsy on a new-born child for medico-legal purposes. While *per se* the fact that a lung sinks is evidence that the child had never breathed, and that if it floats air had entered the lung, there are certain sources of error that must be taken into account. Chief of these is the effect of decomposition which may cause an unexpanded lung to acquire buoyancy enough to float. In this case, however, the bubbles of gas that form beneath the pleura are different in character from the appearance of aeration caused by respiration. The decomposition bubbles are irregular in size and generally are larger than alveoli, and gas formed through decomposition is always in the interstitial tissues and never in the interior of the alveoli. The author then reviews the work of a long series of investigators who have endeavored to establish the scientific value of the test or have suggested modifications of it. Among these is the flotation test of the stomach and upper portion of the intestine. If respiration has taken place air will have entered these cavities and the organs will float, but here again if decomposition has set in the result is unreliable. The author does not attempt from his review of the literature to form conclusions regarding the inferences that may be drawn from the flotation test, but does state that it is still an important feature of the determination of the occurrence or nonoccurrence of a still birth.

Münchener medizinische Wochenschrift, January 15, 1907.

Finding the Round Ligaments in the Inguinal Canal.—Reismann suggests the following expedient to facilitate the isolation of the round ligament in performing the Alexander operation for retroversion of the uterus. Numerous methods for this purpose have already been proposed, but even if the canal is laid open for the entire length, it is frequently difficult to identify the round ligament, owing to the infiltration of the tissues with blood, which very easily takes place and renders it difficult to distinguish the different structures. A simple way of solving the problem is to pick up the entire contents of the canal with a blunt hook and put the parts somewhat on the stretch. The bundle of tissue thus elevated is then pulled apart slightly with two pairs of forceps, and the round ligament will soon be discerned shining through the overlying tissues as a grayish band. The forceps are then used to isolate the structure at this point, and it is caught up on another hook. The first hook is removed and it is now an easy matter to free the ligament from adjoining structures in both directions and to draw out the peritoneal funnel through the internal ring.

The Treatment of Delirium Tremens.—Ganser is of the opinion that it is much better to cut off the alcohol absolutely in cases of delirium tremens than to make any attempt to reduce gradually the amount consumed. He also is averse to the use of sedative drugs, particularly chloral, which he considers is very dangerous even in doses much smaller than those that are frequently recommended. The hot baths and wet packs that have been suggested by several authors are also looked upon with disfavor by Gänser, who states that he has seen collapse and death occur under each of these forms of treatment. In the past sixteen years he has treated 1,051 cases of delirium tremens; during the first eight years 486 patients were treated, with a mortality of 6.37 per cent.; during the succeeding eight years, 565 patients were treated, with a mortality of only .88 per cent. During both of these periods the therapeutic measures were the same in all respects except one, and it is to this one point of difference that the author attributes the great improvement in the statistics. Actuated by the conviction that all persons suffering from delirium tremens either already have weak hearts or that this danger exists, Gänser has adopted the rule of giving digitalis immediately to all patients of this class brought into his hospital. This is kept up until all danger seems to be past, while if at any time evidences of cardiac weakness, such as rapid, small, or irregular pulse, are observed, the customary stimulants, particularly camphor in oil, are given hypodermically. In such cases also ice cold champagne in tablespoonful doses has been found useful, but this is the only condition under which he breaks his rule of abstinence from alcohol. The other features of his plan of treatment comprise careful nursing with abundant feeding and attention to the bowels, isolation being resorted to only when absolutely necessary. Sedatives are very rarely used, as their effect has been found unsatisfactory. In order to facilitate toxin elimination the patient is encouraged to drink freely a 1 per cent. solution of sodium acetate in water to which a little molasses has been added.

Deutsche medizinische Wochenschrift, January 10 *and* 17, 1907.

The Treatment of Large Umbilical Hernias.—Figler says that ordinarily the very large umbilical hernias of new born infants give a bad prognosis. The interferences with the circulation in the displaced organs are apt to cause such serious disturbances of the digestive processes that the nutrition of the child suffers severely. He believes that in these cases radical operation should be resorted to and the earlier the better, because as time goes on it becomes increasingly difficult to secure asepsis and avoid infection of the peritoneum. He describes such a case occurring in a child which at birth weighed two kg. and suffered from a very large hernia into the umbilical cord. The operation was done on the fifth day after birth and the entire liver, together with coils of small intestine, was found in the sac. A radical operation was done and two and a half weeks later the child had more than doubled its weight. Five weeks later the child was seen again and was found to be well nourished and with a healthy cicatrix.

A Simplification of Heller's Test.—Salus speaks highly of the value of Heller's ring test, which he considers the most delicate and certain reaction for albumin in urine, but points out the inconveniences that attend it if it is to be properly carried out. As a simple but thoroughly efficient modification, he suggests the following procedure: A glass plate, such as a microscopic slide, is laid on a black surface, and on this are placed a drop each of nitric acid and of the urine to be tested. If placed close together the drops soon join, and at their line of junction a characteristic film of precipitation will form and gradually produce a milky veil over the fluid which can be clearly discerned against the black background. The test is exceedingly delicate, and in addition to its simplicity of performance, has the advantage that only very small amounts of urine are necessary, a point that is of service in working with scanty urines.

Book Reviews.

Traité de Chirurgie. Par Henri Hartmann, Chirurgie de l'Intestin. Paris: Georges Steinheil, 1907.

The author has succeeded in giving an excellent sketch of the diseases of the intestine requiring surgical aid. The Murphy button is used only in special cases, while, as a rule, the suture is given preference for anastomosis work. The book is well illustrated, and can be highly recommended

De l'Apepsie. Par Henri Français. Paris: G. Steinheil, 1906.

Under the above title Français gives a detailed description of achylia gastrica. The writer gives his own observations and several new experiments relating to the subject. The book may be recommended as profitable reading for the practitioner.

Gesammelte Beiträge aus dem Gebiete der Physiologie, Pathologie und Therapie der Verdauung. Von J. Boas und seinen Schülern. Berlin: Verlag von S. Karger, 1906.

Having been the first to establish a polyclinic for the diseases of the digestive tract in 1880, Boas decided to publish in the present two volumes his and his pupils' works in the last twenty years. Most of Boas' pioneer works are known to every clinician. his essays on the importance of lactic acid in gastric carcinoma; occult hemorrhages in cancer and ulcer of the stomach; mechanical insufficiency of the stomach. In fact, there is hardly an important subject in the field of digestive diseases on which the well-known author has not written something good. In studying the two volumes the reader will thus go through the entire field of the pathology of digestion with great profit to himself, and will congratulate Dr. Boas on his great achievements.

Pulmonary Phthisis. Its Diagnosis, Prognosis, and Treatment. By H. Hyslop Thomson, M.D., Visiting Physician to the Consumption Sanatorium of Scotland, Bridge of Weir, N.B., formerly Medical Superintendent. New York: William Wood & Co., 1906.

The author treats in a most concise manner the whole subject of pulmonary tuberculosis. The work is in three sections, dealing with diagnosis, prognosis, and treatment. In such a brief work it is manifestly impossible to consider either section exhaustively, and in dealing with diagnosis the writer emphasizes particularly abnormalities in signs and symptoms which would lead one to suspect tuberculosis, in preference to giving a detailed consideration of typical cases. He cautions against definite prognosis, and discusses frankly the limitations of open-air treatment. The section dealing with prognosis will be found to contain many points of real value to the general practitioner, and could have been written only by a physician experienced in sanatorium treatment.

In considering the treatment of phthisis, Dr. Thomson has brought out little that is new. Many physicians will differ from him somewhat in the treatment of special symptoms; for instance, the value of the use of antiseptic drugs to overcome secondary invasion by pyogenic bacteria may be questioned. The chapter on specific treatment, though short, is a very interesting summary of recent investigation, and his remarks in regard to tuberculosis in children are worthy of attention.

The Diagnosis of Nervous Diseases. By Purves Stewart, M.A., M.D., F.R.C.P. Physician to Out-Patients at the Westminster Hospital; Joint Lecturer on Medicine in the Medical School; Physician to the Royal National Orthopedic Hospital; Assistant Physician to the Italian Hospital. London: Edward Arnold, 1906.

Diseases of the nervous system are admittedly among the most difficult for the average practitioner to diagnose, and those who see maladies of this description more or less rarely will find the present volume a very useful guide. It is written purely from the standpoint of diagnosis, and without going into any details regarding etiology, pathology, or treatment, the symptoms and physical signs that accompany the various affections of the nervous system are set forth clearly and logically. Several preliminary chapters are devoted to the most important anatomical considerations, and then the different types of phenomena on which the physician bases his deductions are discussed under chapter headings, such as "Coma, Fits, and Other Convulsive Phenomena," "Reflexes," "Disorders of Articulation," etc. Especially useful and interesting are the sections on postures and gaits, and on affections of the sympathetic, and the work closes with a chapter in which the important subjects of lumbar puncture and the cerebrospinal fluid are well presented in the light of recent work. The illustrations are very numerous, and, as they are nearly all original, have the charm of novelty. The author is to be congratulated on his success in achieving his object of presenting a concise and attractive treatise on a difficult subject, and it is a pleasure to recommend it to those interested.

Elements of Practical Medicine. By Alfred H. Carter, M.D., M.Sc., F.R.C.P. Lond.; Professor of Medicine, University of Birmingham; Senior Physician to the Queen's Hospital, Birmingham; Emeritus Professor of Physiology, Queen's College, Birmingham; Consulting Physician to the Corbett Hospital, Stourbridge, the Bromsgrave Hospital, the Smallwood Hospital, Redditch, and Guest Hospital, Dudley. Ninth Edition. London: H. K. Lewis, 1906.

This is an excellent compendium of the practice of medicine, well adapted to the needs of the advanced student, the busy practitioner, and anyone who wishes to review the broad facts of medicine without going into the minute details of pathology or a discussion of the differing and often conflicting views of various writers. The author describes the various diseases in turn, following the generally accepted teaching and avoiding reference to other authorities. In this way much ground is covered in a few pages. The book is not a treatise on medicine, but rather a plain narrative of the course of disease, with suggestions regarding the management of the patient, and a statement of the generally accepted treatment. Following an introductory chapter on General Pathology are chapters on Specific Infectious Diseases, General Diseases, Diseases of the Blood and Glands, of the Respiratory, Circulatory, Alimentary, Urinary, and Nervous Systems, and of the Skin. There are no illustrations; they are not needed in a work of this kind, and their omission is commendable in these days of many picture books. A practical and not too long therapeutic index completes the work. We like this book, and we think others will find it a useful guide to medical practice; indeed, others must have found it so, for the work is now in its ninth edition

The Diseases of the Nose, Throat, and Ear. By Charles P. Grayson, M.D., Clinical Professor of Laryngology, Medical Department, University of Pennsylvania. Second Edition, revised and enlarged. Philadelphia and New York: Lea Brothers & Co., 1906.

The first edition of this manual was favorably noticed in these columns. The various topics have been brought up to date in the new edition and some excellent colored plates added. The characteristic feature of the work is, in our opinion, a wise selection of therapeutic measures, so that the beginner is not confused by too many suggestions. So also particular stress is laid on the relations of nasal and throat to other bodily functions. The writer impresses one as a good, all-around physician, as well as a skilled rhinologist. He realizes that there is a medical as well as a surgical side to the question of nose, throat, and ear therapy. We know of no better work for the student or the practitioner beginning this special line of work. Of the 518 pages of text (excluding formulary and index), 225 are devoted to the nose and accessory cavities, 96 to the nasopharynx and pharynx, and 195 to the ear.

Abdominal Pain. Its Causes and Clinical Significance. By A. Ernest Maylard, M.B., B.S. (Lond.), Surgeon to the Victoria Infirmary, Glasgow; late Examiner in Surgery to the University of Glasgow, and Victoria University, Manchester; formerly Demonstrator of Anatomy, Guy's Hospital, London, and ex-President of the Glasgow Pathological and Clinical Society; Author of a "Treatise on the Surgery of the Alimentary Canal." Second Edition (revised). London: J. & A. Churchill, 1906.

In view of the fact that, although pain is one of the commonest symptoms of disease, it is also, owing to its subjective nature, one of the most difficult to interpret, it is rather strange that medical writers have not devoted more attention to the subject. Compared with other topics, it would seem that semeiographers had given it but scant consideration, and any contribution to a study of its nature and practical bearing deserves the gratitude of the profession. What may be accomplished in this field by a thoughtful investigator is well illustrated by the present work, which is devoted to the symptom as it occurs in the abdominal region. Owing to the thoroughness with which the origin of referred pains has been taken up, the scope of the volume is much greater than its title at the first glance indicates, particularly as pain in the sides, and dorsal, lumbar, and sacral regions is included. While such chapters as those on post-operative pains caused by different types of causes, such as incisions and ligatures, flatulence, peritonitis, and adhesions, and the character of certain operations are of especial interest to surgeons, most of the book should be found of great value by internists as well. By means of a series of well-compiled tables, the work is made very convenient for use as a reference book.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON PEDIATRICS.

Stated Meeting, Held December 13, 1906.

DR. MATTHIAS NICOLL, JR., IN THE CHAIR.

Splenomegaly, with Special Reference to Etiology.—Dr. ELI LONG presented three cases of splenomegaly. Cases 1 and 2 were twins, boy and girl, nineteen months old. The father and mother were healthy, and gave no specific history. These were the last of nine children, all living except two, one having died from diphtheria, the other having been killed in an accident. The mother had never had a miscarriage. These babies were breast-fed entirely till one month of age, when they were given supplemental bottles of Borden's bottled milk, modified, not pasteurized or sterilized. The children were kept out of doors. They had never before been ill. On examination the most striking feature was their very pale skins, especially that of the girl. They were well nourished, with slight rickets. The spleen of the little girl extended about 2½ inches below the free border of the ribs, that of the boy about 1 inch. The livers were slightly, if at all, enlarged. The spleens were firm, but not hard to the touch. Examination of the blood showed the following: Specimen from the girl, according to Dr. L. B. Goldhorn's examination, revealed many nucleated red cells, half of which were megaloblastic in type. There was marked poikilocytosis, a marked lack of hemoglobin, but no malaria. The red cells numbered 2,200,000, the color index was 0.5, the hemoglobin 22 per cent., leucocytes 18,700. Differentially, the polymorphonuclears 32.1 per cent., lymphocytes 49.8 per cent., transitionals 15.1 per cent., eosinophiles 1.0 per cent., basophiles .8 per cent., and myelocytes 1.2 per cent. The specimen from the boy was practically the same, with less anemia and less leucocytosis. Case 3. This boy, two years old, was the youngest of three children, the others living and well. The parents were German, healthy, no miscarriages, or other specific history. The baby had been entirely breast-fed, although the mother had menstruated for the past six months. The first tooth appeared at twelve months. There was a great deal of bowel trouble, especially each summer. The child had been sickly and weak from birth, and had never walked. Examination showed an extremely rachitic infant, much emaciated. He had six teeth. He was markedly rachitic, and the epiphyses were greatly enlarged. The spleen extended two inches below the costal arch, was fairly hard to the touch. The liver was enlarged to within a finger's breadth of umbilical level. Examination of the blood by Dr. Goldhorn showed a very grave secondary anemia. There was a very marked variation in size of the red cells, a moderate poikilocytosis, many normoblasts, a few megaloblasts, and kariokynesis was present. The red cells numbered 3,200,000, the color index was 0.8, hemoglobin 52 per cent., leucocytes 18,200; no malaria. Differentially, the polymorphonuclears 42.2 per cent., lymphocytes 42.5 per cent., mono and transitionals 9.2 per cent., eosinophiles 6.1 per cent., basophiles 1.0 per cent., myelocytes 0.0 per cent.

Dr. Long said that these cases of enlarged spleens and anemia came to one even in private practice with this condition already established, and one did not know how or when it began and could only surmise as to the probable cause. In a few one got a definite history of malaria, but one did not anticipate such a result from malaria, nor in a very large majority of malarial cases did one get it. He asked who would feel justified in saying that infants with healthy brothers and sisters, with no family history of syphilis, and no other evidences of specific disease, had congenital syphilis which had caused the present condition? And as to certain kind of diet as an etiological factor, it was just as indefinite.

DR. CHARLES HERRMAN believed that the cases presented by Dr. Long pointed to the correctness of the theory of the congenital anomaly of the blood-forming organs. He had seen three sets of twins with this condition. When there were two children the amount of iron was insufficient, and one child might be more anemic than the other because one received a smaller amount of iron through the placenta.

A Case of Congenital Syphilis.—DR. CHARLES HERRMAN presented this child, nine weeks old, who at birth had edema, especially marked on the dorsum of the feet and hands. According to the mother, the condition of their first child, who died when eleven days old, was similar to the condition of this, their second child. The patient was poorly nourished, weighing 4 pounds and 4 ounces, temperature 97.4°, skin dry, somewhat brownish, buttocks excoriated, a slight rhinitis, and a congental systolic murmur over the precordium. No specimen of urine was obtained, but so far as he was able to judge there was no lesion of the kidneys. The mother had been given bichloride of mercury, and there had been some improvement, the child having gained some in weight and the edema having diminished somewhat. He now expected to place the baby on antisyphilitic treatment.

Urinal for Infants.—DR. HENRY DWIGHT CHAPIN presented this urinal which made the collection of infants' urine comparatively easy.

Pyelitis in Infancy and Childhood, with Remarks on the Urine.—DR. LOUIS FISCHER read this paper, and said that in a series of cases observed by him three groups of symptoms stood out prominently: (1) The fever, intermittent in character, progressive emaciation, and constipation or coprostasis; (2) bed-wetting and pains evidenced by crying while urinating, passing of small quantities of urine at a time, as though afraid to pass more because of pain, absence of fever throughout the whole course of the disease; (3) distinct digestive disturbances mostly marked by the passage of scybalous masses and feces intermingled with shreds of membrane, and with it marked anorexia, fever very rarely present. The diagnosis of these cases was made by the microscopical examination of the urine. It emphasized the importance of securing a specimen of urine in every case of infantile disease. The presence of continued fever in an infant was a very distressing symptom, and when it assumed the type so well known as an intermittent fever a diagnosis could only be made by resorting to laboratory aids in conjunction with the current methods of physical diagnosis. All cases seen by him had shown marked disturbances of the gastrointestinal tract. In one of the cases Dr. Fischer reported the noteworthy features were that the child was playing out of doors and in apparent good health up to the day he saw this case. Had it not been for the catarrhal rhinitis the family would not have sent for him, although the child had enuresis nocturna for several days prior to the rhinitis. This case illustrated forcibly the necessity of examining the urine for morphological elements, and also showed that a pyelitis could exist without causing severe systemic disturbances, as this child had no fever and nothing that indicated kidney disease. Three other cases were reviewed. A review of these four cases showed the following: First, the pyelitis presented a variety of symptoms resembling intermittent fever with marked exacerbations and remissions in the temperature. Second, that pyelitis was occasionally met with in infancy as an afebrile type, and were it not for the presence of the enuresis no symptoms associated with the genitourinary tract would have been present to direct attention to the kidneys. It was well to remember that pus might be found in the body without showing the presence of fever; hence too great stress should not be placed on the absence of fever as a guide to the presence or absence of pus. An interesting point in connection with these cases was that they all occurred in female children.

One should never rely upon the examination of one specimen of urine as a positive guide to diagnosis. The general plan of treatment consisted in rest in bed, good ventilation, sponge or warm baths. To allay the pain during urination and the irritation of the genitals a warm demulcent bath was used. The diet consisted of milk diluted with alkaline waters, cereals, fruits and fruit juices, and gelatin puddings. Meat and eggs were excluded during the acute stage. The use of phosphate of sodium or bicarbonate of potassium in five-grain doses, taken with an abundance of water, was recommended. A urinary antiseptic in moderate doses three times a day was also prescribed in most cases.

Dr. Henry Dwight Chapin said that it was very difficult to make a diagnosis of pyelitis from the clinical history alone, and he emphasized the importance of constantly examining the urine. There was no doubt that many cases that puzzled them so were cases of pyelitis. At the hospital by means of the instrument for collecting infants' urine he had been enabled to make diagnoses of pyelitis which could not have been made from the clinical symptoms. He said he had not been as successful as Dr. Fischer in collecting urine by the old methods; frequently the catheter would make excursions into the vagina before getting into the urethra.

Dr. Henry Illoway said that he had read about the diagnosis of pyelitis, but he was yet in the dark as to how to make a differential diagnosis; he asked if there was anything distinctive about pyelitis, and why they called it pyelitis.

Dr. E. L. La Fetra showed a chart with an intermittent curve of temperature. The baby when first seen was one of fourteen months, and had been ill one week. The course of the disease was five weeks. He presented this chart in connection with Dr. Fischer's paper.

Dr. Charles G. Kerley said that the five cases he had had differed from those of Dr. Fischer. All were under eighteen months of age, and all were girls. There was a marked onset in all, and the excursions of temperature were very wide, varying from three to five degrees. In all cases the colon bacillus was found.

Dr. Matthias Nicoll, Jr., said he was puzzled to know upon what Dr. Fischer based his diagnosis, after examining the microscopical charts of the patients recorded in the paper.

Dr. Louis Fischer said that every specimen of urine was sent to Dr. Sondern and every case showed pus and blood, a diagnosis of pyelitis being made positively. He thought the cases reported by him were typical ones. He had never seen such cases as reported by Dr. Kerley with such an acute onset with chills. He recalled one case of pyelitis of severe form; the child was playing on the street, and he was called because the child sneezed so and coughed. Examination of the urine revealed the presence of pus.

Dr. L. Emmett Holt reported the case of a child seven or eight months old with pyelitis in which chill was the most striking symptom. The patient would have a chill at four o'clock, the teeth would chatter, and two hours later the temperature would be 106°. The chills recurred sometimes twice a day. This was a symptom that he had not seen often. In another case the amount of pus in the urine was the largest he ever saw, being about one-sixth the volume of the urine on standing. He believed that chills were rather exceptional, but did occur occasionally with severity.

Report of Three Epidemics of Measles, with Particular Reference to Koplik's Symptom and its Relation to the Rash and the Initial Fever.—Dr. Charles J. Dillon presented a communication with this title. (See page 294.)

Election of Officers.—The election of officers of the Section resulted in the choice of the following: *Chairman*, Dr. Charles Rice; *Secretary*, Dr. Eli Long.

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting, Held December 27, 1906.

Dr. Arnold Sturmdorf in the Chair.

Case of Ovarian Pregnancy.—Dr. Sidney D. Jacobson presented this specimen, one of true primary ovarian pregnancy. Such an impregnation, he said, was supposed to take place by the union of the spermatozoa with the ovum in the follicle, and was an exceedingly rare condition. The first report of such a case was made in the seventeenth century. In 1835 Velpeau published a work on this subject when ovarian pregnancies were believed to be common, and he showed that the cases reported to be instances of ovarian pregnancy were not entitled to that name. The Germans had always admitted the possibility of ovarian pregnancy, but the English had opposed that view. In 1891 Bland Sutton was the last to hold out that there was any such thing as ovarian pregnancy. So many cases were reported that in 1878 a gynecologist postulated the formulæ, viz., (1) the tube had to be normal; (2) the fetal sac must occupy the position of the ovary; (3) the ovarian ligament must connect with the uterus; (4) definite ovarian tissue must be found in the sac of the growth. The specimen showed a little fetus in a small cavity almost in the center of the ovary. The woman was 28 years old, married eight years. She menstruated at 14 and about every thirty days since. She became pregnant in the third year of her married life and had a normal full term pregnancy and delivery. She was curetted when seven months married for stenosis of the os. She had had three miscarriages since. On the 11th of October she was supposed to menstruate. Four days later she began to "spot." On the 20th a severe hemorrhage occurred, and she passed a piece of flesh the size of a walnut, whitish in color, probably decidua. Dr. Jacobson saw her on the 21st, advised her removal to the hospital, and, on the 23d, twelve days after her supposed period had taken place, operated. The operation was not at all difficult. The diagnosis of ectopic pregancy had been comparatively easy.

Dr. George H. Balleray believed that time should be taken to have the specimen thoroughly examined by a committee to find out if the specimen presented by Dr. Jacobson was truly one of ovarian pregnancy. These cases were so extremely rare that his diagnosis should not be accepted until a more thorough examination had been made by fully qualified experts.

Dr. H. N. Vineberg did not believe that they should accept the specimen as one of ovarian pregnancy on macroscopical evidence alone. There should first be a thorough examination of the specimen by two or three experts.

Specimen of Calcified Ovary.—Dr. Henry C. Coe presented this specimen. The patient from whom it was removed was 29 years old, single, and was admitted to the hospital October 23. She had never been pregnant. She was told ten years ago that she had a tumor. She had no symptoms until two years ago. She had a large fibroid which extended to within two inches of the umbilicus. She had no pain. The only indication for operation was the rapid growth of the tumor and hemorrhage. Operation was performed on October 25, a supravaginal hysterectomy being done. The appendix was also removed. Both ovaries were diseased, the right being cystic, the left calcified, as shown by the specimen. She was discharged cured on the twenty-fifth day. An interesting point arose as to whether this was an osteoma of the ovary. Such a case had never been reported. Calcification of the corpus luteum was a rare condition. He presented such a specimen in 1899. The condition was first described many years ago. Dr. Coe then read extracts from the report of Williams' case. The specimen presented showed the ovary to be filled with calcareous material, and was probably of inflammatory origin.

Dr. H. N. Vineberg said he could add one more to the list. This woman had inflammatory symptoms for two

years, and he found the uterus retroverted; behind the uterus a hard nodule was to be felt which he thought to be a fibroid undergoing calcification. At operation this proved to be an ovary; both ovaries were involved. He excised the calcareous part and left some ovarian tissue behind, and the woman had menstruated since. The pathologist's report proved this to be an undoubted case of calcified ovary.

Dr. SIDNEY D. JACOBSON said that it would be well to bear in mind the possible existence of calcified ovaries in making radiographs for the purpose of determining calculi in the kidney or ureters.

Conservative Surgery in Severe Inflammatory Affections of the Uterine Adnexa.—Dr. HIRAM N. VINEBERG read this paper (See page 217.)

Dr. HENRY C. COE said that when this subject came up he thought of his experience extending back twenty years, when he began his work, and observation on a large number of cases on whom he had performed the radical operation, *i.e.* removal of tubes and ovaries. No one with such an extended experience with young women 25 or 30 years old, from whom both ovaries had been removed, could help but be impressed with the serious consequences which followed this radical procedure. To-day they believed it to be absurd the wholesale way the ovaries were sacrificed, not only for disease but when prolapsed. Some of these individuals had climacteric disturbances which lasted ten or twenty years. Operators to-day agreed that it was best, whenever possible, to leave in some of the ovarian stroma. Numerous cases of pregnancy following this operation have not been reported. Dr. Coe always tried to save some ovarian stroma, but with little hope of pregnancy following; if the patient menstruated, he felt very well satisfied; it was very rare for pregnancy to follow. In most of these cases the end of the tube became occluded. No matter how careful one was in the technique, or how great an experience one might have, there was a great uncertainty as to what the ovarian tissue would do afterwards; some patients menstruated normally for two or three years, and then menstruation would cease. In young married women, with chances of conceiving, it was very disappointing for menstruation to cease, even though there be no climacteric disturbances. Every effort should be made to save ovarian tissue, even in cases where the ovaries were buried in adhesions, or in pus cases; but in so doing he sutured them so that they would not drop down. In some cases menstruation had gone on normally, although there were no chances of pregnancy. Dr. Coe said he wished to protest against the growing habit of extirpating the whole uterus for fibroids. He had five or six cases in his office with absolutely no symptoms, not even pressure symptoms, and in all extirpation of the uterus had been advised. Dr. Coe now consistently practised conservative surgery, but not so much so as formerly.

Dr. JAMES N. WEST felt that they knew comparatively little about this subject, and he could not agree with the statement that it had been thoroughly worked out. Many authors had reported pregnancy following conservative work on the tubes and ovaries, but they all failed to note the nature of the operation. He believed that when they did conservative work upon the tubes and ovaries the operation should be carefully recorded and a very careful record of the case kept. The accumulation of such knowledge would be of great value. Dr. West had practised conservative surgery all his professional career, but he believed there was much of interest on this subject not yet worked out. In looking over the literature on this subject, he was unable to find recorded a single case where, after a double pyosalpinx, the patient had become pregnant. In general it was wise, in women before the age of forty, to leave the ovaries behind when possible. He said they might divide these cases up into groups: Women approaching the menopause, women in the active period of menstrual life, and women who had passed the menopause. In women approaching the menopause he would always consider the possibility of preserving the tubes and ovaries, and here the element of personality entered. Sentiment should not be wasted over tubes and ovaries in women of 40 or 45 years of age. If they were sufficiently diseased to demand opening the abdomen, remove them. In women passed the menopause, if the abdomen was opened to remove a uterine tumor, then he believed in removing both ovaries. He emphasized the importance of leaving a portion, if possible, of one ovary when operating upon women in active menstrual life. But if one ovary was the seat of a benign tumor, the other being comparatively healthy, he believed it best to remove the entire ovary with the benign tumor. If one or the other ovary became the seat of malignant disease it was wise not only to remove both ovaries and tubes, but much of the broad ligament and uterus as well, unless the disease was semi-malignant.

Dr. SAMUEL W. BANDLER said that in the case of papillomata or papillomatous degeneration of an ovarian cystoma the other ovary should be removed, even if it appeared normal. In the case of unilocular or multilocular cystomata or dermoid cysts, the other ovary, if apparently normal, should be retained. If, however, it showed structural changes, resection should be practised in younger women. In older women it should be removed. When, however, involvements of the tubes and ovaries with adhesions, or marked inflammatory affections of the adnexa, were the indication for operations, he believed the question entered a different phase. The character of the surgical procedure was materially altered by the indications which prompted the operation. The indications were sterility and pain. He said he had yet to perform his first conservative abdominal operation solely for primary or secondary sterility without pain or without some malposition of the uterus, or without tangible involvement of the adnexa. That pregnancy might result after mild inflammatory affections of the tubes was shown by uterine pregnancy following or complicating ectopic gestation, but, in such cases, adhesions were not present. They represented, in his opinion, very mild cases of salpingitis. Again, there were many cases in which the opposite tube was markedly involved by inflammation, so that he had removed the tube on the opposite side, because of its involvement and closure by adhesions. In any involvement of the tube and ovary associated with adhesions when pain furnished the indication for operation, the tubes were the main consideration. It should not be forgotten that the tubes furnished the path for peritoneal infection. If the tubes were closed by adhesions, the value of resection was associated with the danger that the inner half of the tube might continue the formation of new adhesions, and only complete removal of the entire tube would insure against this complication. If no adhesions existed he failed to see the value of resection of the tube. The results that were desired in the performance of conservative surgery were pregnancy, freedom from pain, and from constitutional annoyance. A conservative operation on the tubes, with retention of ovarian tissue, assured the continuation of menstruation, the possibility of pregnancy, and freedom from constitutional annoyance, but did not assure freedom from future adhesions with pain. He said he was not aware of a single case where a patient, primarily sterile for years, and in whom conservative operation in the form of resection of the tubes or the formation of new ostia were done, had resulted in pregnancy. He was not aware of a case where conservative surgery was done for purulent involvement of both adnexa with adhesions that was followed by subsequent pregnancy. If they contrasted the relative advantages and disadvantages of the conservative and radical procedures, the results in the performance of conservative operation for an inflammatory condition were poor as regarded future pregnancy, they were very uncertain as to freedom from pain or extension of inflamma-

tion. He believed that ovarian tissue should be left or transplanted if one of the ovaries showed no marked involvement. He had yet to observe in his cases incurable annoying symptoms resulting from double ovariotomy; almost all these annoying symptoms of the artificial climacteric might be overcome by the early and consistent use of ovarin. All conservative operations for inflammatory conditions were accompanied by the risk of no cure of the symptoms, and possibly an extension of the inflammation in the structures operated upon, or extension of the inflammation to structures not touched at operation. Therefore, the only legitimate reason was the desire for maternity. Any patient desirous of pregnancy, and who was willing to take the risk of failure, or to chance a possible return of the annoying symptoms, was entitled to consideration. Only the practical experience of individual surgeons who compiled and compared the results of *like cases* would eventually furnish a definite basis for future action. In his hands the immediate results of conservative operations on the adnexa for inflammatory conditions had been most unsatisfactory.

Dr. G. H. Balleray said that cases like those referred to by Dr. Vineberg were not to be taken as illustrations of conservatism, but rather of extreme radicalism. Opening the abdomen to puncture two or three small cysts of the ovary, and possibly resect a very slightly diseased tube, was anything but conservative. Those cases should be let alone. Cases of pyosalpinx should not be operated upon during the acute stage, as the operation was liable to be followed by fatal peritonitis. Later, when the diseased adnexa had become walled off from the peritoneal cavity, and the pus was more or less sterile, the operation was much safer. In nearly all bad cases of pyosalpinx the ovaries were so badly diseased that their complete extirpation was imperative. In these cases the patient was an invalid as the result of the pathological condition of the uterine appendages, and they should be removed *in toto*. The object of an operation in such cases was to cure the patient—not to increase her capacity for breeding. Leaving a portion of diseased ovary in the pelvis in such cases, in the hope of a subsequent pregnancy, was sentimental nonsense. The fear of a stormy artificial menopause following the ablation of badly diseased appendages was not well founded. He had never seen violent nervous symptoms occur after such operations. The rule was that the patients were cured of their sufferings, and gained rapidly in flesh and strength. So far as sterility was concerned, those patients were already sterile before the operation was performed, having been literally unsexed by the destructive disease of their uterine appendages, and the operation did not aggravate their condition in that regard. A few years ago normal ovaries were removed by the peck for all sorts of nervous ailments, real and imaginary, which were supposed to be due to some sort of occult telepathy originating in the ovaries. Many of these patients were made worse by the operation. Removal of *normal* ovaries might be followed by serious perturbation of the nervous system, but when the ovaries were so diseased that their function in the economy was destroyed, their removal was not followed by any violent nervous disturbance. Patients who ceased to menstruate after the removal of their appendages were, according to his experience, better off than those who continued to menstruate. In all cases of double pyosalpinx both tubes and ovaries should be removed. He indorsed the protest entered by Dr. Coe as regards the removal of the uterus for small fibroids the size of a walnut. He had seen several such cases, and in some the patient had died as the result of the operation. This was pure surgical quackery, and should be condemned by all reputable members of the profession.

Dr. George H. Mallett said he distinctly remembered the many discussions on radicalism and Dr. Lawson Tait's statement that when one ovary was diseased the other always became so, and should, therefore, be removed. Then the pendulum swung the other way, and now it was customary to save all that was possible in operations upon the uterine adnexa. A great difficulty was in determining whether or not an ovary was diseased. In determining upon the proper treatment many things were to be considered, such as the age of the individual and the condition of each ovary. All to-day practically practised conservative surgery on the tubes and ovaries, and he did not know an operator who removed tubes or ovaries if it was possible to save them.

Dr. Sidney D. Jacobson referred to the mutilating operations that were being done and the ablation of the cervix uteri, and said the tendency of gynecologists was to amputate the cervix because of few tears.

Dr. Arnold Sturmdorf said that conservatism for him did not exist, and that he removed all that he thought to be actually diseased.

Dr. H. N. Vineberg said that these cases which had been objects of conservative treatment, and which gave so much trouble were those which had been subjects of much speculation, and had been permitted to go on for three, four, five, or six years, becoming hopeless because seen so late, that was, after the process had gone on for years. In case of pus tubes, they ought to be removed, as this removed the source of a possible subsequent infection. Even though the pus be walled off and become sterile, toxins might develop which would set up inflammatory changes in the surrounding structures. With regard to conservative surgery in cases of malignant disease, he recalled a case seen ten years ago, a woman with an enormous carcinoma of the ovary. He removed that one. She later was married, gave birth to a child, and had been well ever since. Where one had a clean-cut case, with the growth not extending through the capsule, one would be safe in leaving the ovary. With regard to the occlusion of tubes after plastic operation, he said all knew the difficulty of occluding a tube when it was desired to prevent pregnancy.

Election of Officers.—*Chairman*, Dr. Howard C. Taylor; *Secretary*, Dr. William S. Stone.

SECTION ON MEDICINE.

Stated Meeting, Held January 15, 1907.

Dr. Warren Coleman in the Chair.

Two Cases of Cerebrospinal Meningitis.—Dr. C. H. Lewis reported these cases.

The first case was in a male, 54 years old, a laborer. Two days prior to his admission to St. Vincent's Hospital he was well and working. That night he returned home with a slight headache. The following day he became irritable and violent and was sent to the hospital as a case of "acute mania." On admission his temperature was 101°, pulse 80, and respirations 34. He required forcible restraint, and, during his lucid moments, complained of headache. The next day his temperature had dropped to normal, his pulse was 82, and respirations were 24, and he said he felt well and wanted to go home. He was urged to remain until the next day. That night a stuporous state came on, and the next day he had injected conjunctivæ, slight photophobia, some mental irritability. The temperature was 100°. Aside from these symptoms there was nothing to indicate the gravity of his condition. The white count was 18,000, with 81 per cent. polynuclears. The following day deep coma supervened. A lumbar puncture removed half an ounce of very turbid fluid which contained many pus cells and a large number of the *Diplococcus intracellularis*. He died that evening, just four days after the first symptoms were noted. This case was notable, first, in the absence or late appearance of characteristic symptoms, and, secondly, in the disappearance of all physical, mental, and psychical signs and symptoms thirty-six hours before death, and, thirdly, the rapid and virulent course during the last twelve hours.

The second case was that of a 'longshoreman, 42 years old, who was admitted to St. Vincent's Hospital, December 11, 1906, with a history of vomiting, and complaining of great pain in the metatarsophalangeal joint of the left little toe. He had been ill nine days prior to admission (the last five days in bed) with gastric pain, constant vomiting, and general indefinite and dissociated symptoms looking toward an influenzal infection as much as anything. He had taken no alcoholic drinks for the past six months. On the night before entering the hospital he was awakened by stabbing pains in the little toe joint, which he described "as though hot irons were driven into it." The temperature was 103.6°, pulse 100, and respirations 28. The leucocytes numbered 10,000. A soft systolic heart murmur was heard at the apex, but nothing further was found relevant to this report on careful physical examination. From the swollen and reddened joint, the sudden and characteristic onset of the pain, the chronically deformed finger joints, and two small trophi in the right ear, he made the diagnosis of acute gout, attended with a gastritis of unknown cause. On the night of the following day the right elbow joint was seized with an attack similar to the one affecting the toe joint, and on the next day the elbow presented relatively a small tophi in the right ear, he made the diagnosis of acute hospital, the vomiting ceased. No new joints were involved, but the pain and inflammation persisted in those already affected. The temperature, which had risen to 104° shortly after admission, had remained about this point. On account of the heart murmur and the rising leucocyte count, now 18,000, with polynuclears 80 per cent., a blood culture was made with negative results. The next day, the fourth in the hospital, symptoms presented which suggested the true nature of the disease. There appeared a mild delirium, unequal and stiff pupils with a moderate injection of the right conjunctiva, herpes labialis, tache cérébrale, and slight neck rigidity. On the day following the delirium he became noisy, then stuporous. Photophobia, sluggish pupils, increased injection of right eye, and neck rigidity were added to the picture. Up to this time the left eye was unaffected. The next day, the sixth in the hospital, the left pupil was greatly dilated. There was a conjunctivitis, opacity of the cornea, and choroidoiritis, and the eye resembled an extreme case of panophthalmitis, with considerable protrusion of the eyeball. Purpuric spots appeared on the trunk, and for the first time a Kernig sign was elicited in the right leg only; this was not marked. The leucocytes now numbered 24,000. A lumbar puncture withdrew two and a half ounces of a clear fluid under considerable pressure, which, after centrifuging, revealed a small number of the *Diplococcus intracellularis*. The patient died shortly after midnight, the last temperature being 104.8°, the highest point reached, the lowest being 103.6° on admission. Dr. Lewis was inclined to believe that true gout complicated the specific infection, although the possibility of an infective arthritis must be considered. The complications of the disease, the late appearance of cardinal symptoms, and the entire absence of some, the protracted and excessive vomiting, twelve days in all, a symptom alluded to by Osler, the rapid destruction of the left eye, the continuously high temperature, and the clearness of the spinal fluid and sparse number of diplococci so late in the disease, made the case of particular interest, and emphasized once more the protean nature of this dread disease.

Acid Intoxications.—Dr. C. G. S. Wolf read this paper.

Dr. Max Einhorn spoke of some experiments he had made some time ago to find out how certain animals acted in different solutions of sugar, etc. In the first experiments he added simply acid and water, and at the end of twenty-four hours the frogs became comatose, could not move, and acted very differently from others. Upon the addition of alkalies those frogs became lively and recovered their normal condition. He believed without doubt that some conditions of acidosis could be cured by the addition of alkalies. The acid condition in diabetes did not necessarily depend upon starvation. He thought it was rather due to the increase in the animal food, which, as a rule, was taken in diabetes. All vegetables were rich in potassium salts, and animal foods were rich in sodium salts. A patient on a vegetable diet would excrete alkaline urine; on a meat diet, acid urine. Therefore, if the defect was due to lack of alkalies, the patient should be fed on alkaline material. Of course, if there was some present, there might be other factors causing it.

Dr. Heinrich Stern said that he was glad that somebody else had expressed similar opinions as regards the acetone bodies, as he himself had done for a number of years. However, to substitute another substance for the hypothetical toxicity of the betaoxybutyric acid derivatives, as Dr. Wolf had done in bringing forth oxalic acid, did not bring us one step further in the proper understanding of acid intoxication, acidosis, or acid coma. Oxalic acid was not present in the blood serum of diabetics when in the comatose state in any larger amounts than one would expect in any morbid state in which metabolism was more or less seriously interfered with. With much greater justification could we fasten the train of untoward phenomena in so-called acidosis to formic acid, or at least to the various exceedingly toxic combinations of formic acid which might arise in the organism in considerable amounts. He had again pointed out in his book on the autotoxicoses that betaoxybutyric acid was not that important factor in the production of acid intoxication, so called, which it was supposed to be by Studelmann and others, and especially by von Noorden. All acid principles seemed to contribute toward the causation of an acidosis, which latter, however, was a term by no means denoting the true condition prevailing at the time in the body fluids. At the foundation of acidosis, Dr. Stern maintained, there was a faulty alkali supply. Normally, the withdrawal of alkali was soon followed by a new supply. Such a renewal did not take place, or to an insufficient degree only, in fasting organisms or in underfed individuals. On the other hand, how were they to explain the alkali deficit in the face of abundant and even overabundant alkali ingestion? He had made up his mind long ago that we could experiment until doomsday without being able to fasten the various comatose states to a chemically-active poison or poisons. He was of the opinion, which he had already maintained in a number of articles and discussions, that the entire question involved was of a physicochemical or physicoelectrical nature, that bodily activity, etc., was dependent upon an intrasystemic osmotic equilibrium, and that the concentration of the body liquids and the degree of ionic activity displayed therein were without a shadow of a doubt at the bottom of most comatose conditions.

Dr. Joseph C. Roper said that at the New York Hospital acid intoxication was not taken as the cause of death. It was merely an associated condition.

Dr. Wolf, in reply, said that one might get up acidosis, but not an acid intoxication. They usually distinguished sharply between acidosis, which was a distinct entity, and acid intoxication, which was not a distinct clinical entity. If a subject was fed on saccharal and carbohydrate material, the subject would have acidosis, but not acid intoxication.

Dr. Roper accepted the correction.

Localized Intestinal Atonies and Their Relation to Neurasthenia.—Dr. G. R. Lockwood read this paper. He said that constipation was roughly divided into two classes, the spastic and atonic form, and he gave in a few words the characteristics of these two forms. He then called attention to a form, standing between these two, a definite clinical entity, a form commonly seen, productive of annoying symptoms of intestinal toxemia and neurasthenia, a form readily amenable to treatment, to which he applied the name "cecal atony." Examination showed the first part of

the ascending colon to be given some consideration. The latter could not be readily palpated, but palpation elicited a splashing and succussing sounds quite pathognomonic. Especially were these sounds elicited by rapid vibratory movements with the knuckles of the flexed fingers perpendicularly applied. The transverse portion was normally palpable, but no succussions were noted, unless an enema was given just prior to the examination. The descending portion might be readily rolled under the finger, well contracted, often as much as in the spastic form. In this form he had a local stasis in the cecum, with normal propulsion in the transverse and descending portion. The stools varied in a number of ways. There might be intermittent attacks of diarrhœa, the stools being large, fermenting, fetid, often of acid reaction, and containing mucus and small hardened feces, like uncooked beans in a porridge. This appearance to him was quite characteristic. The variety of stool was due to an exacerbation of the local catarrhal colitis of the cecal region, due to the prolonged presence of fermenting fecal masses in the ascending colon. In the majority of the cases there was a history of the overuse of cathartics. In the form of cecal atony, autointoxication symptoms of intestinal origin were common, varied, in many cases resulting in prolonged invalidism. It was the cause of a great many cases of so-called "primary neurasthenia." The treatment consisted of diet, drugs, massage, and irrigations, and attention to the general nervous state. Without reference to any catarrhal state of the bowels, the diet should consist of coarse particles of food and in a generous amount of fat. The worst diet was a "milk" one. The drugs to be used were the muscle tonics. Irrigations were indicated when there were marked autointoxication symptoms. The ordinary form of high enema, in which two to four quarts of water were introduced at one time into the bowel, was to be deplored, for it overdistended the bowel and increased the atony. He showed the section the irrigation outfit he used. Massage constituted the most important part in the treatment. The general health must always demand the closest and most detailed attention.

Dr. MAX EINHORN called attention to the recognition of the atonic condition of the bowel by means of the *x*-ray. The treatment which would be the most successful was the one directed towards building up the system. He gave plenty of good, plain food, with an increase in the amount of vegetables which would increase the food residue and give more for the bowel to work on. Massage was of great value.

Dr. A. ROSE said that in cases of atony there was a relaxation of the abdominal muscles. The function of these muscles was twofold: first, to keep the abdominal organs in their proper physical condition, and, secondly, to control the innervation and circulation. When the abdominal muscles were relaxed there must be ptosis of different organs; if then these muscles be supported, these organs would return to their proper position and remain there. Therefore, in these atonies one should consider the treatment of the abdominal muscles. The books said nothing about these muscles controlling the innervation and circulation, and the importance of these abdominal muscles had not been considered sufficiently.

Dr. S. J. MELTZER said that from a clinical point of view the observation was interesting, that possibly there should be an area in the colon, which behaved differently from the balance of the colon. He was interested in this statement, because they knew there was a physiological basis for that assumption. Cannon found years ago that the ascending part of the transverse colon behaved differently, inasmuch as there was both antiperistalsis and peristalsis. These observations were made on cats; later on Smith and Elliot found this to be so in some, but not in all animals. Dr. Lockwood had apparently observed this antiperistalsis. He called attention to the fact that the part of the bowel supplied by the hypogastric and that supplied by the sacral plexus behaved differently. Eserine he considered to be one of the worst drugs to give; he had seen it given to a dog, and it resulted in a distention of the gut to the size of an arm. With regard to the atonic condition of the colon in connection with neurasthenia, if one treated the colon to cure the neurasthenia, one must assume the condition of the colon to be a cause of the neurasthenia. That was only one symptom of neurasthenia. As yet they did not know what neurasthenia was, but he did not believe that the condition in the colon was a cause of it.

Dr. LOCKWOOD said that he had had splendid results from the administration of eserine in these cases, and placed much reliance upon it.

Diagnosis and Treatment of Acute Intestinal Obstruction.—Dr. MAX EINHORN presented this communication. The recognition of this condition was based on the absence of stool and flatus in conjunction with symptoms of collapse, tympanites, abdominal pains and vomiting of intestinal contents. The fecal vomiting of ileus must be differentiated from that of hysteria, as well as of cholelithiasis and nephrolithiasis, which often took a similar course. In both these diseases the symptoms of occlusion would moderate after relieving the pain. In true ileus this would not be true, nor, although the pain might be relieved, the inability to pass wind as well as abdominal distention would remain. If the obstruction was in the small intestine all the symptoms were usually much more violent than in occlusion of the large intestine; furthermore, there was in the beginning a marked indicanuria. In obstruction of the large intestine fecal vomiting occurred late, and indicanuria usually on the fifth day of the disease. If the occlusion was well down in the large intestine, the quantity of water which might be introduced into the rectum gave a clew as to the location. The use of the *x*-ray fifteen to twenty hours after giving bismuth was of value in localizing the obstruction. In all cases of obstruction absolute rest should be insisted upon, rest in bed, abstinence from food, absolute rest for the bowel. The patient might be given small quantities of water or small pieces of ice, but no food. If the obstruction was high up in the small intestine, small nutrient enemata were permissible. Subcutaneous salt-water injections were the best means of introducing liquids into the system. Cathartics were to be avoided unless one was fairly certain that he was dealing with a case of obturation by gallstones or hard fecal masses. In order to put the bowel at rest it was best to use morphine or opium. During the last two years the use of atropine in ileus had again been revived and highly recommended. Dr. Einhorn had used it during the past two years in six cases, of which four got well. He believed atropine should be tried in every case. If the patient was not too much weakened, lavage of the stomach should be given, and was of special value if the obstruction was high up. Injections of rather large quantities of water under considerable pressure was at times of value, although some clinicians did not recommend this. Massage was of special benefit when the obstruction was due to fecal impaction, and electricity in the dynamic form of ileus. In grave cases, in which the tympanitic distention was of a very high degree, in which all procedures had failed, and in which operation could not be done, an attempt to relieve the bowel by means of puncture was justifiable.

Dr. S. J. MELTZER and Dr. G. R. LOCKWOOD discussed the paper.

Renal Decapsulation in Eclampsia.—This has already been advocated by several authorities, and Polano also speaks strongly in its favor, although he admits that he is unable to explain the manner in which the operation brings about its results. He recommends that in all cases of severe eclampsia bilateral renal decapsulation should be resorted to, and urges that too much time be not allowed to elapse before making use of this measure, as its chances of effectiveness are greatly increased the earlier it is employed.—*Zentralblatt für Gynäkologie.*

Books Received.

While the MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

ANIMAL MICROLOGY. By MICHAEL F. GUYER, Ph.D. 8vo, 240 pages, illustrated, muslin. The University of Chicago Press, Chicago. Price, $1.75.

THE PRACTICAL MEDICINE SERIES. By GUSTAVUS P. HEAD, M.D. Vol. VIII. 12mo, 358 pages, muslin. The Year Book Publishers, Chicago.

THE DIAGNOSIS OF NERVOUS DISEASES. By PURVES STEWART, M.A., M.D., F.R.C.P. 8vo, 380 pages, illustrated, muslin. Edward Arnold, London.

PROGRESSIVE MEDICINE, A Quarterly Digest. Edited by HOBART AMORY HARE, M.D. 8vo, 349 pages, illustrated, paper. Lea Bros. & Co., New York. Per annum, $6.

THE PRACTICE OF OBSTETRICS. By J. CLIFTON EDGAR. Third edition, 4to, 1071 pages, illustrated, muslin. P. Blakiston's Son & Co., Philadelphia.

TROPICAL MEDICINE. By THOMAS W. JACKSON, M.D. 8vo, 536 pages, illustrated, muslin. P. Blakiston's Son & Co., Philadelphia. Price, $4.00.

THE HARVEY LECTURES. Delivered under the auspices of the Harvey Society of New York by various authors. 8vo, 337 pages, illustrated, muslin. J. B. Lippincott Company, Philadelphia.

A TREATISE ON ORTHOPEDIC SURGERY. By ROYAL WHITMAN, M.D. Third Edition, Revised and Enlarged. 8vo, 871 pages, illustrated, muslin. Lea Brothers & Co., New York.

SYLLABUS OF LECTURES ON HUMAN EMBRYOLOGY. By WALTER PORTER MANTON, M.D. Third Edition, Revised and Enlarged. 12mo, 130 pages, illustrated, muslin. F. A. Davis Co., Philadelphia.

CONSERVATIVE GYNECOLOGY AND ELECTROTHERAPEUTICS. By G. BETTON MASSEY, M.D. Fifth Revised Edition. 8vo, 467 pages, illustrated, muslin. F. A. Davis Co., Philadelphia.

SELF-PROPELLED VEHICLES. By JAMES E. HOMANS, A.M. 8vo, 598 pages, illustrated, muslin. Theo. Audel & Co., New York.

TUMORS OF THE CEREBRUM. By various authors. 8vo, illustrated, muslin. Edward Pennock, Philadelphia.

PHYSICAL CHEMISTRY IN THE SERVICE OF MEDICINE. By Dr. WOLFGANG PAULI. First Edition. 12mo, 156 pages, muslin. John Wiley & Sons, New York.

DISEASES OF CHILDREN. By GEORGE M. TUTTLE, M.D. Second Edition, Revised and Enlarged. 8vo, 392 pages, muslin. Lea Brothers & Co., New York.

WHO'S WHO 1907. Fifty-ninth year of issue. 12mo, 1957 pages, muslin. The Macmillan Company, New York.

STUDIES IN THE BACTERIOLOGY AND ETIOLOGY OF ORIENTAL PLAGUE. By E. KLEIN, M.D., F.R.S. 8vo, 301 pages, illustrated, muslin. The Macmillan Co., New York.

A PRACTICAL TREATISE ON MATERIA MEDICA AND THERAPEUTICS. By JOHN V. SHOEMAKER, M.D., LL.D. Sixth Edition thoroughly revised. 8vo, 1255 pages, muslin. F. A. Davis Co., Philadelphia.

THE TOXINS AND VENOMS AND THEIR ANTIBODIES. By EM. POZZI-ESCOT. First Edition. 12mo, 101 pages, muslin. John Wiley & Sons, New York.

DIE THERAPIE DER HAUT-UND GESCHLECHTSKRANKHEITEN FÜR PRAKTISCHE ARZTE. 12mo, 318 pages, illustrated, muslin. Von Dr. Reinhold Ledermann, Verlag Von Oscar Coblentz, Berlin.

DISEASES OF THE STOMACH AND INTESTINES. By BOARDMAN REED, M.D. Second Edition. 8vo, 1021 pages, illustrated, muslin. E. B. Treat & Co., New York. $5.00.

VOICE PRODUCTION IN SINGING AND SPEAKING. By WESLEY MILLS, M.A., M.D., F.R.C.S. 8vo, 282 pages, illustrated, muslin. J. B. Lippincott Co., Philadelphia, Pa.

WOMAN. By BERNARD S. TALMEY, M.D. 8vo, 228 pages, illustrated, flexible morocco. The Stanley Press Corporation, Publishers, N. Y.

TUMORS, INNOCENT AND MALIGNANT. By J. BLAND-SUTTON, F.R.C.S. 8vo, muslin, 675 pages, illustrated. Fourth Edition. W. T. Keener & Co., Chicago. $500.

ANATOMY, PHYSIOLOGY, PATHOLOGY, DICTIONARY. W. A. EVANS, M.S., M.D., ADOLPH GEHRMANN, M.D., WILLIAM HEALY, A.B., M.D. Vol. IX. Series 1006. 12mo, 236 pages, illustrated, muslin. The Year Book Publishers, Chicago. $1.25.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

MEDICAL EXAMINING BOARD OF VIRGINIA.

June 19, 20, 21, and 22.

CHEMISTRY.

1. Define valence, base, a salt, dialysis, alloy.
2. Describe the chemistry of alcohols and ethers.
3. Give formula of ammonia. The sources and uses of ammonia in medicine and the arts.
4. Give chemistry of respiration, showing what is inhaled, what is exhaled, and how the gases enter and leave the blood.
5. Show by equation how nitric acid is formed by the action of sulphuric acid on potassium nitrate.
6. Complete the following equations:

$$AgNO_3 + NaCl. =$$
$$4HF + SiO_2 =$$

TOXICOLOGY.

1. Give symptoms and treatment for carbolic acid poisoning.
2. State symptoms of chronic arsenic poisoning with treatment for same.
3. Describe the difference between alcoholic, uremic and opium coma.

MEDICAL JURISPRUDENCE.

1. Define medical jurisprudence.
2. Give the reliable signs of death.
3. How would you distinguish between insanity and idiocy.

OBSTETRICS, GYNECOLOGY, AND PEDIATRICS.

1. What signs are brought out by abdominal palpation in the last stages of pregnancy, and their relative value?
2. Detail briefly the hygienic measures necessary for the successful issue of pregnancy?
3. Define pelvimetry; what measurements obtained thereby should determine interference?
4. What circumstances, other than pelvic contractions, may cause dystocia?
5. Describe the management of delivery in breech presentations.
6. Describe briefly an operation for relaxed pelvic outlet.
7. Detail the symptoms and possible terminations of pelvic peritonitis.
8. Treatment of rectovaginal fistula.
9. What therapeutic agents should be cautiously exhibited in infancy, and mention some that they bear proportionately better than adults.
10. Mention the most important diseases of the larynx in children, giving the causes for their greater danger.

SURGERY.

1. Give the diagnosis and treatment of acute osteomyelitis.
2. Give the cause and treatment of varicose ulcers.
3. Name the surgical diseases common to man and the domestic animals.
4. Give the differential diagnosis between (a) concussion of the brain so-called, (b) fracture of the skull, and (c) rupture of the middle meningeal artery.
5. Give briefly Cohnheim's hypothesis as to the origin of tumors
6. What is hydrocele? Give diagnosis and treatment.
7. Give the nature and treatment of Pott's fracture.
8. Name the dangers and give the treatment of carbuncle.
9. Give the causes and treatment of cystoureteropyelitis.
10. Name the dislocations of the elbow. Give the symptoms and treatment of the backward dislocation.

It is proposed in this department to publish from time to time the examination papers of the various State Boards, in order that a candidate may become familiar with the character of the examination and so in some measure free himself in advance from the nervousness and dread which the unknown inspires. In furtherance of the same object answers to some of the questions will be published in order to show the candidate what the examiners expect of him. Not all the questions of all the papers will be so treated, for the answers to many, especially in the anatomical papers, are obvious or can be found in the index of any text-book on the subject; the answers to other questions, especially in the surgical papers, must sometimes be omitted because of the space they would demand. The candidate for a medical license will not find in these answers a short and easy road to success in the examination, for he is not likely to meet the same questions in the papers placed before him by the examiners. The object of publishing the questions and answers is only, as noted above, to acquaint the candidate with the general character of these examinations and to inspire him with confidence in the result of his trial.

ANATOMY.

1. Describe the upper extremity of the tibia.
2. Describe the ligaments of the hip joint.
3. Describe the external oblique muscle, including a description of the superficial abdominal ring.
4. Give the commencement, termination, relations, and branches of the brachial artery.
5. Give the commencement, termination, and relations of the internal jugular vein.
6. Describe the duodenum.
7. Give origin, course, and distribution of the median nerve.
8. Name the muscles, nerves, and arteries severed by a cross section of the thigh at the junction of the middle with the lower third.

EMBRYOLOGY.

1. At what stage of embryonic life does the development of the alimentary canal commence, and from what layer of the blastoderm is it formed?
2. What changes occur in the vascular system of the fetus at birth?

PRACTICE, ETIOLOGY, AND DIAGNOSIS.

1. To what disorders are persons of a lithemic diathesis most prone? Outline dietary and treatment of the lithemic state.
2. State early symptoms and causes of tuberculosis.
3. State physical symptoms and diagnosis of asthma.
4. In what conditions is severe pain a prominent symptom, and to what extent does localized pain aid recognition?
5. State cause and management of acute milk infection.
6. Describe the stools of acute enteritis, typhoid, obstructive jaundice.
7. Differentiate between scabies and pustular eczema.
8. What is aphasia? Give cause, and differentiate between the ataxic and aphasic forms.
9. Give symptoms and treatment of chorea.
10. What drugs influence character of stools?
11. What clinical significance attaches to cardiac arythmia?
12. Cause and treatment of stomatitis.

PATHOLOGY.

1. Name the phenomena comprised (changes which occur) in an inflammatory process.
2. State the systems through which, and how necrosis is produced by disordered nutrition.
3. What is leucopenia, and in what important disease does it occur?
4. What is an exudate, and what is the character of the exudate in lobar pneumonia, bronchopneumonia, and acute peritonitis?
5. Name the histological elements to be found in a fibro-osteochondromyxo sarcoma. By what route do the metastases of sarcoma generally occur?
6. Give the morbid anatomy of acute articular rheumatism (rheumatic fever), and name the possible complications of this disease.

BACTERIOLOGY.

1. Define and illustrate the terms, aërobic, obligate, pleomorphous, and sporogenous, and name and explain the two varieties of chemotaxis.
2. Describe the microorganism of anthrax, and give its pathogenicity.
3. What special culture medium is required for the growth of the gonococcus? Give the pathogenicity of the gonococcus.

NEUROLOGY.

1. Give the etiology of locomotor ataxia.
2. Give the symptoms of cerebral apoplexy, and name the conditions the coma of which may be simulated by an apoplectic stroke.
3. Give the prognosis in tubercular meningitis and in epidemic cerebrospinal meningitis, and the general indications of treatment in the latter.

MATERIA MEDICA.

1. Name, with dose of each, the preparations of salicylic acid; give its physiological action, and state in what form it is to be administered.
2. Give the preparations of belladonna; describe the toxic effects and give antidotes.
3. Give the chief alkaloid of cinchona, its dose, and its physiological action.
4. Name the preparations of the chlorides of mercury; give dose and differentiate the physiological action of each.
5. Name the mineral acids and mention the special properties of each.
6. Give the physiological action of opium; name its most important alkaloids and give dose of each.

THERAPEUTICS.

1. Into what two classes are bitters divided? Give therapeutic uses. Contraindications. Time of administration.
2. How may the two chlorides of mercury be administered? Give their therapeutic uses. In bilious attacks, when you give calomel, what remedy often used to allay nausea would you be particular not to give?
3. Why would you use a strong solution of arsenic when applied over large surfaces? In giving Fowler's solution in increasing doses what untoward symptoms would indicate that the dose should not be further increased?
4. (a) Give the therapeutic application of drugs in the different stages of pneumonia; (b) give the comparative value of chloroform and ether as an anesthetic.
5. (a) Describe the therapeutics of iodine and its salts; (b) what are the therapeutic uses of diuretics?
6. Prescribe a local application for erysipelas, for rhustoxicodendron poisoning. Name some remedies used for epistaxis, croup, singultus, ptyalism. Write a prescription for night-sweats of phthisis, for ascites.

PHYSIOLOGY.

1. What are the uses of the blood, and what is the difference between arterial and venous blood?
2. What is the effect of the pneumogastric nerve upon the heart?
3. What is meant by the term vesicular murmur?
4. What are the characteristics of peptones?
5. Name the pancreatic ferments, and describe the action of each.

HYGIENE.

1. Name the qualities desirable in water for drinking and domestic purposes.
2. Give best methods for disinfecting a house in which there has been a case of smallpox.
3. What precautions should be taken by a physician attending a case of diphtheria.

HISTOLOGY.

1. What is meant by endochondral formation of bone, and describe process briefly.
2. Describe formation of an artery, giving coats.

LARYNGOLOGY.

1. What are the symptoms, course, and treatment of acute laryngitis?
2. Give the diagnosis and treatment, both general and special, of laryngismus stridulus.
3. Give the symptoms, course, some common complications, and treatment of acute follicular tonsillitis.

RHINOLOGY.

1. What anatomical arrangements within the nares render the treatment of chronic rhinitis difficult?
2. Give the most generally accepted theory of predisposing and exciting causes of hay fever, and describe its symptoms.

OPHTHALMOLOGY.

1. What are the macroscopical appearances of the most common forms of keratitis, and the appropriate treatment?
2. Give the causes, symptoms, and general and local treatment of trachoma.
3. Give cause, symptoms, and treatment, both prophylactic and remedial, of ophthalmia neonatorum.

OTOLOGY.

1. Define tinnitus aurium and give the causes of it.
2. Give briefly the diagnosis and treatment of acute otitis media.

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

MEDICAL EXAMINING BOARD OF VIRGINIA.

June 19, 20, 21, *and* 22, 1906.

CHEMISTRY.

1. *Valence* is the combining power of an atom of an element as compared with that of an atom of hydrogen.

A *Base* is a compound which on entering into double decomposition with an acid produces a salt and water.

A *Salt* is a substance derived from an acid when the hydrogen of the latter has been partially or completely replaced by an electropositive element or elements (a metal or metals).

Dialysis is the process of separating colloids from crystalloids.

An *Alloy* is a substance composed of two or more metals.

2. An *Alcohol* is the hydroxide of a hydrocarbon radi-

cal. Alcohols are monoatomic, diatomic, and triatomic, according to the saturating power of the radical. They are also classified as primary, secondary, and tertiary. The primary alcohols are characterized by the group CH_2OH, and yield on oxidation, first an aldehyde, and then an acid. Secondary alcohols contain the group CHOH, and on oxidation yield a ketone. The tertiary alcohols contain the group COH, and when oxidized two acids or ketones are produced, each with fewer carbon atoms than the original alcohol. Ethyl alcohol, $CH_3.CH_2OH$ is a primary alcohol; isopropyl alcohol, $CH_3CHOH.CH_3$ is a secondary alcohol; tertiary butyl alcohol, $(CH_3)_3COH$ is a tertiary alcohol. Ethene glycol, $CH_2OH.CH_2OH$ is a diatomic alcohol, and glycerol, $CH_2OH.CHOH.CH_2OH$ is a triatomic alcohol.

An *Ether* is the oxide of a hydrocarbon radical. In *simple ethers* the radicals are the same, as $(C_2H_5)_2O$, ethyl ether; in *mixed ethers* the radicals are different, as $CH_3.C_2H_5.O$, methyl ethyl ether. A *compound ether* is a substance derived from an acid by replacing the hydrogen of the acid by a hydrocarbon radical, thus $C_2H_5.NO_2.O$, ethyl nitrate or nitric ether; compound ethers are now generally called *esters*.

3. Ammonia; formula is NH_3; sources, in nature from the decomposition of animal or vegetable matter containing nitrogen and hydrogen; it is manufactured from ammonium chloride and calcium hydroxide according to the equation: $2NH_4Cl+Ca(OH)_2=2NH_3+CaCl_2+2H_2O$. It is used as a respiratory stimulant, a circulatory stimulant, a counter-irritant; it neutralizes acids, making definite salts known as ammonium salts, which are formed by the direct combination of the ammonia with the acid. It is also used in the artificial preparation of ice.

5. $KNO_3+H_2SO_4=KHSO_4+HNO_3$.

6. $AgNO_3+NaCl=AgCl+NaNO_3$.

$4HF+SiO_2=SiF_4+2H_2O$.

TOXICOLOGY.

1. *Symptoms*:—buccal mucous membrane is whitened and hardened; vomiting; burning pain in mouth, esophagus, and stomach; pulse and body temperature are lowered; the pupils are contracted; collapse, and finally death. The urine may become dark. *Treatment*:—emetics, white of egg, stimulants. Alcohol is said to be antidotal.

2. *Symptoms*:—malaise, anorexia, drowsiness, photophobia, conjunctivitis, eczema, weakness, emaciation, local paralysis, stripping off of the skin and dropping of the hair. *Treatment*:—remove the causes, give freshly prepared ferric hydroxide, castor oil, diuretics.

3. In *alcoholic coma* there may be an odor of alcohol on the breath, the patient can generally be aroused by shouting in his ear, there is no paralysis, the pupils are normal or dilated, respiration is practically normal, the pulse is first rapid and later feeble, and the skin cool.

In *uræmic coma* there may be a urinous odor to the breath, the urine is scanty and contains albumin, there is slow pulse with high arterial tension, the pupils are usually small and equal, respiration is deep and may be quickened, the body temperature may be above normal or subnormal.

In *opium coma* the pupils are contracted, respiration is slow, pulse slow and full, body temperature is normal or subnormal, there may be the odor of laudanum on the breath.

MEDICAL JURISPRUDENCE.

1. Medical jurisprudence is the application of the knowledge of any of the branches of medicine to the problems and requirements of the law.

2. The complete and permanent cessation of circulation and respiration, rigor mortis, loss of body heat, pallor of the body, putrefaction.

3. Idiocy is congenital.

OBSTETRICS, GYNECOLOGY, AND PEDIATRICS.

9. The following should be cautiously exhibited in infancy:—cocaine, opium, apomorphine, jaborandi, the coal-tar derivatives, acids, and some of the preparations of iron. The following are relatively well tolerated:—arsenic, belladonna, chloral, calomel, bromides, iodides, quinine, and acohol.

SURGERY.

3. Tuberculosis, hydrophobia, actinomycosis, glanders, anthrax, septicemia, pyemia, cancer and other tumors, cleft palate and hare-lip.

4. (a) *Concussion of the brain* is characterized by sudden onset, the patient is unconscious but can be aroused, the muscles are relaxed and flaccid, the pulse weak and slow, respirations faint and irregular, the skin pale and cold, the sphincters relaxed, the pupils are equal and react, the temperature is subnormal but is the same on both sides of the body.

(b) In *fracture of the skull* (at the base) there will be hemorrhage and escape of the cerebrospinal fluid either from the nose, into the orbit, from the ear, or into the loose cellular tissue of the mastoid or occipital region, there will be indications of injury to one or more of the cranial nerves, such as loss of smell, blindness, ptosis, strabismus, facial paralysis, internal deafness.

(c) In *rupture of the middle meningeal artery* there will be first a concussion with its accompanying unconsciousness; this will be followed by a temporary return to consciousness, lasting from a few minutes to an hour or more; this is succeeded by a gradually increasing drowsiness, ending in coma.

5. Cohnheim suggested that, owing to some slight developmental errors, small portions of embryonic tissue become misplaced and surrounded by cells belonging to a different blastodermic layer. These misplaced cells lie dormant, but are still alive; and later some blow or other irritant acts as a stimulus and starts them growing, and the result is a tumor.

8. The dangers of carbuncle are:—hemorrhage, septic phlebitis, septic clots or emboli, septic meningitis, exhaustion, septicemia, or pyemia.

ANATOMY.

8. *Muscles*:—Vastus externus, vastus internus, crureus, rectus femoris, sartorius, gracilis, adductor longus, adductor magnus, biceps, semimembranosus, semitendinosus.

Arteries:—Femoral, profunda femoris, external circumflex, comes nervi ischiadici.

Nerves:—Anterior crural, middle cutaneous, internal cutaneous, long saphenous, external cutaneous, obturator, great sciatic, lesser sciatic.

EMBRYOLOGY.

1. The development of the alimentary canal begins at a very early period of embryonic life, the enlargement which later becomes the stomach being noticeable as early as the fourth week. The alimentary canal is derived from all three layers of the blastoderm, but particularly from the hypoblast and the mesoblast.

2. The hypogastric arteries shrink and become impervious, the foramen ovale closes, the eustachian valve atrophies, the ductus arteriosus closes, the ductus venosus becomes obliterated, the umbilical vein becomes obliterated.

PRACTICE, ETIOLOGY, AND DIAGNOSIS.

1. They are most prone to gout, arteriosclerosis, chronic interstitial nephritis, aneurysm, angina pectoris, acute inflammations, apoplexy, and certain skin diseases, such as urticaria, eczema.

4. Severe pain is a prominent symptom in:—passage of calculi, burns, aneurysms, angina pectoris, colic, gout, whitlows, otitis media, tic douloureux, and acute inflammations.

Localized pain is of some value as an aid to diagnosis, but an indication of the different conditions in which such pains are found would take up too much space; it should, however, be remembered that pain is sometimes wrongly referred, as pain in the knee in hip joint disease, or the pain of herpes zoster, which is referred to the skin.

6. In *acute enteritis*, the stools are fluid or semifluid, and contain particles of undigested food, bile, and tiny specks of mucus.

In *typhoid*, the stools are thin, yellowish ("peasoup"), and vary in number from one or two up to ten or twelve in twenty-four hours.

In *obstructive jaundice*, the stools are clay-colored, pasty, and offensive.

7. In *scabies*, there will be the presence of burrows and of the itch-mite, the eruption will generally be found on the anterior surface of the wrists, about the umbilicus, in the mammary region in females, or around the genitals in males; there is intense itching; it is communicable, and is readily amenable to treatment.

In *pustular eczema*, there are no burrows and no itch-mites; as a rule, poorly nourished or delicate children are attacked, and the eruption is found on the face and the scalp; after the pustules rupture, yellowish or greenish crusts form; the itching is variable.

8. *Aphasia* is the inability to express ideas by either speech or writing. It is caused by lesions of the cortical centers, and is not due to lesions of the peripheral nerves or of the organs concerned in speech or writing.

In *ataxic aphasia*, there is loss of speech, owing to lack of coördination of the muscles concerned in voice production.

In *sensory or amnesic aphasia* there is loss of word memory, which may or may not exist in connection with ataxic aphasia. There are several varieties of aphasia.

10. Calomel and colchicum may color the stools green; rhubarb, senna, and santonin may cause a yellow color; iron, bismuth, and manganese may give a black color; logwood may cause a red color; and sulphur may cause a very offensive odor.

11 Cardiac arrhythmia has no particular clinical significance, unless it accompanies some disease. According

to Butler (*Diagnostics of Internal Medicine*), search should be made for one or more of the following:—(1) Valvular cardiac disease, especially mitral lesions, in which it is usually, but not always, a sign of beginning failure of compensation, passing in many instances into delirium cordis; simple dilatation, chronic myocarditis, sclerosis of the coronary arteries, and fatty degeneration; possibly obscure changes in the cardiac ganglia, and overstrain or impaired nutrition in wasting diseases or long-continued fevers. (2) Poisons circulating in the blood, such as alcohol, coffee, tea, tobacco, digitalis, aconite, and belladonna, or the toxines of the infectious diseases, especially of typhoid fever and pneumonia. (3) Diseases of the intracranial contents, meningitis, hemorrhage, abscess, softening, concussion, and not infrequently mental excitement. (4) Neurasthenic conditions resulting from excesses or overstrain. Brief attacks of moderate arrhythmia are not uncommon in neurotic individuals, following even a slight departure from their usual habits in food, drink, or exertion. (5) Digestive disturbances, acute or chronic, and jaundice or constipation, particularly if associated with an unusually hypochondriacal frame of mind. (6) More rarely arthritis deformans, exophthalmic goiter, and renal disease.

PATHOLOGY.

2. Necrosis is produced by disordered nutrition through two systems:—(1) the circulatory, by means of anemia and of stasis of blood and lymph; and (2) the nervous, by means of both vasomotor impulses and the reflexes.

3. Leucopenia is the condition in which the number of white blood cells is diminished; sometimes the term is used to denote merely absence of leucocytosis. It occurs in:—typhoid, tuberculosis, pernicious anemia, pneumonia, cachexia, inanition, measles, influenza, malaria.

4. An *exudate* is the material that has passed through the walls of the vessels into the surrounding tissues, as the result of inflammation. In *lobar pneumonia*, the exudate consists of fibrin, red blood cells, epithelial cells, polynuclear leucocytes, and diplococci, in the stage of red hepatization; in the stage of gray hepatization the fibrin and red bood cells have disappeared, and the exudate now consists mainly of leucocytes and some pus cells.

In *bronchopneumonia* the exudate consists of serum, leucocytes and endothelial cells; occasionally there may be a few red blood cells and a trace of fibrin.

In *acute peritonitis* the exudate is serous or purulent, and is generally fibrinous.

5. Fibrous tissue, bone, cartilage, mucous tissue, and connective tissue of embryonic type. The metastasis is by way of the blood-vessels.

6. The synovial membrane and ligaments are swollen and congested; the synovial fluid is increased in amount, is turbid, and may contain lymph: the cartilages are roughened and may become ulcerated or eroded; the joint may suppurate or there may be a false ankylosis; in the blood there is a diminution in the number of the red cells, and an excess of fibrin. The possible complications include:—endocarditis, pericarditis, occasionally myocarditis, pleurisy, chorea, tonsillitis, pneumonia, cerebral disturbances such as convulsions or delirium, and certain skin eruptions as urticaria.

BACTERIOLOGY.

1. *Aërobic* bacteria are such as require the presence of oxygen in order to live and grow. Most bacteria are aërobic.

Obligate means necessary; and the term is used in opposition to *facultative*. Obligate aërobic bacteria are such bacteria as cannot exist without oxygen; whereas facultative aërobic bacteria are such as thrive better in the presence of oxygen, but still can manage to exist without it.

Pleomorphous bacteria are such as assume more than one form.

Sporogenous bacteria are bacteria in which reproduction takes place by sporulation instead of by the more usual method of fission.

Chemotaxis is the property by virtue of which certain living cells approach *(positive chemotaxis)* or move away from *(negative chemotaxis)* certain other cells or substances.

3. The special culture medium required for the growth of the gonococcus is human blood serum.

NEUROLOGY.

1. Locomotor ataxia is a disease of adult life; is more common in men than in women; is more common in cities than in the country; syphilis is believed to be the most frequent direct cause; alcoholism, injury, exposure to cold and wet, have all been urged as causes, but they are not now assigned so important a place as etiological factors as was formerly the case.

MATERIA MEDICA.

1. *Preparations* of salicylic acid are:—sodium salicylate, dose gr. xv; lithium salicylate, dose gr. xv; ammonium salicylate, dose gr. iv; strontium salicylate, dose gr. xv; phenyl salicylate (salol), dose gr. vijss; bismuth subsalicylate, dose gr. iv. *Physiological action:*—antiseptic, irritant, diaphoretic, diuretic, antipyretic, and cholagogue. It is *best administered* in the form of one of the salts, preferably sodium salicylate.

2. *Preparations* of belladonna:—the extract, the fluid extract, tincture, ointment, the plaster, and the liniment. Atropine, with its oleate and sulphate, and homatropine hydrobromide.

Toxic effects:—dryness of the mouth and throat, thirst, drowsiness, dysphagia, face flushed, pupils much dilated, eyes prominent, numbness and partial paralysis of the extremities, and there may be delirium and coma.

Antidotes:—There is no antidote; pilocarpine is the best physiological antagonist, and opium will counteract the effect on the pupils.

4. The only preparation of corrosive sublimate or mercuric chloride is the lotio hydrargyri flava, or yellow wash. The preparations of calomel or mercurous chloride, are compound cathartic pills, dose two pills; lotio hydrargyri nigra, or black wash; and compound pills of antimony, or Plummer's pills, dose one to three pills.

5. The mineral acids are:—hydrochloric, sulphuric, nitric, nitrohydrochloric, and phosphoric acids.

THERAPEUTICS.

1. The two classes into which bitters are divided, are:—(1) simple bitters, and (2) aromatic bitters. Their *therapeutic uses* are:—to promote appetite, to increase gastric secretion, to act as tonics to the mucous membrane of the alimentary tract, in atonic dyspepsia, in chronic gastritis, in sea-sickness, and as vehicles for the administration of other drugs and preparations. *Contraindications:*—acute gastritis and gastric ulcer. Bitters should be administered shortly before meals.

5. (b) The therapeutic uses of diuretics:—to remove liquid from the body tissues or cavities, to increase the elimination of waste products and of poisons, to dilute the urine, and to maintain the excretory action of the kidneys.

6. For *erysipelas*, equal parts of ichthyol, ether, and collodion. For *rhus toxicodendron poisoning*, grindelia robusta, four drams to a pint of water. For *epistaxis*, aconite, adrenalin, witchhazel, vinegar, tincture of the chloride of iron, plugging the nares. For *croup*, ipecac, apomorphine, lactic acid, hydrogen dioxide, potassium citrate. For *singultus*, morphine, chloroform, ether, strychnine, ice. For *ptyalism*, acids, astringents, potassium iodide, borax, belladonna.

For *night sweats of phthisis:*—

℞ Acidi camphorici.....ʒij
Alcoholis.....ʒj
Mucilaginis acaciæ.....ʒiss
Syrupi aurantii corticis.....q.s. ad. ʒiij Misce.

Signa:—One dessertspoonful one hour before the sweat is expected.

For *Ascites:*—℞. Pulveris digitalis
Pulveris scillæ aa gr. xxx Misce.
Fiat in pillulas no. xxx

Signa:—One every four hours.

PHYSIOLOGY.

1. The uses of the blood are to supply nourishment to, and to take away waste matters from, all parts of the body. The red corpuscles supply the tissues with hemoglobin; the white corpuscles serve as a protection to the body from the incursions of pathogenic microorganisms, they take some part in the process of the coagulation of the blood, they aid in the absorption of fats and peptones from the intestine, and they help to maintain the proper proteid content of the blood plasma.

Arterial blood is bright red in color, contains more oxygen, less carbon dioxide, more water, and is slightly warmer; *venous blood* is purple in color, contains less oxygen, more carbon dioxide, less water, and is slightly cooler (except in the hepatic vein).

2. The pneumogastric nerve conveys inhibitory impulses from the medulla to the heart.

3. By the term *vesicular murmur* is meant the peculiar breathing sound which is heard when listening over the vesicular tissue of the lungs.

4. Peptones are characterized by being very soluble in water, hygroscopic, easily dialyzed, and they respond to none of the ordinary proteid reactions with the exception of the biuret reaction, with which they give a red color.

5. The pancreatic ferments are (1) *trypsin*, which changes proteids into proteoses and peptones, and afterwards decomposes them into leucin and tyrosin; (2) *amy-*

lopsin, which converts starch into maltose; (3) *steapsin*, which emulsifies and saponifies fats; and (4) a milk-curdling ferment. All of these act in an alkaline medium only.

HYGIENE.

1. It should be colorless, odorless, cool, limpid, soft; it should have an agreeable taste, neither salty nor sweet nor flat; it should dissolve soap readily without formation of a curdy precipitate, it should contain not more than about twenty-five to thirty grains of solids per gallon, and should not be polluted with sewage.

OTOLOGY.

1. Tinnitus aurium is the name given to any subjective sounds heard in the ear. The chief causes are:—neurasthenia, impacted cerumen, otitis, and other ear diseases; Ménière's disease, obstruction of the Eustachian tube, anemia, leukemia, cerebral hyperemia and anemia, arteriosclerosis, gout, digestive disorders, excessive use of alcohol or tobacco, and the use of certain drugs such as quinine or salicylic acid.

BULLETIN OF APPROACHING EXAMINATIONS.†

STATE.	NAME AND ADDRESS OF SECRETARY.	PLACE AND DATE OF NEXT EXAMINATION.		
Alabama*	W. H. Sanders, Montgomery.	Montgomery.	March	1–6
Arizona*	Ancil Martin, Phoenix	Phoenix	April	1
Arkansas*	F. T. Murphy, Brinkley	Little Rock	April	9
California	Chas. L. Tisdale, Alameda	San Francisco	April	16
Colorado	S. D. Van Meter, 1723 Tremont Street, Denver	Denver	April	2
Connecticut*	Chas. A. Tuttle New Haven	New Haven	March	12
Delaware	J. H. Wilson, Dover	Dover	June	18
Dis. of Col'bia	W.C.Woodward, Washington.	Washington	April	11
Florida*	J. D. Fernandez, Jacksonville.	Jacksonville	May	15
Georgia	E. R. Anthony, Griffin	Atlanta	April	—
Idaho	J. L. Conant, Jr., Genesee	Boise	April	2
Illinois	J. A. Egan, Springfield	Chicago	April	17
Indiana	W. T. Gott, 120 State House, Indianapolis	Indianapolis.	May	28
Iowa	J. F. Kennedy, Des Moines	Des Moines	March	19
Kansas	T. E Raines, Concordia	Topeka	June	11
Kentucky*	J. N. McCormack, Bowling Green	Louisville	April	23
Louisiana	F. A. La Rue, 211 Camp St., New Orleans	New Orleans	May	9
Maine	Wm. J. Maybury, Saco	Portland	March	5
Maryland	J. McP. Scott, Hagerstown	Baltimore	June	—
Massachusetts*	E. B. Harvey, State House, Boston	Boston	March	12
Michigan	B. D. Harison, 205 Whitney Building, Detroit	Ann Arbor	June	11
Minnesota	O. E. Linjer, 24 South Fourth Street, Minneapolis	St. Paul	April	2
Mississippi	J. F. Hunter, Jackson	Jackson	May	14
Missouri	J. A. B. Adcock, Warrensburg.	St. Louis / Kansas City	April	16
Montana*	Wm. C. Riddell, Helena	Helena	April	—
Nebraska	Geo. H. Brash, Beatrice	Lincoln		
Nevada	S. L. Lee, Carson City	Carson City	May	6
N. Hamp're*	Henry C. Morrison, State Library, Concord	Concord	July	9
New Jersey	J. W. Bennett, Long Branch	Trenton	June	18
New Mexico	B. D Black, Las Vegas	Santa Fe	June	3
New York	C.F.Wheelock Univ.of State of New York, Albany.	New York, Albany, Syracuse, Buffalo.	May	21
N. Carolina*	G. T. Sikes, Grissom	Morchead City	May	—
N. Dakota	H. M. Wheeler, Grand Forks.	Grand Forks	April	2
Ohio	Geo. H. Matson, Columbus	Columbus	June	11
Oklahoma*	J W. Baker, Enid	Guthrie	March	26
Oregon*	B. E. Miller, Portland	Portland	April	—
Pennsylvania	N. C. Schaeffer, Harrisburg.	Philadelphia / Pittsburg,	June	—
Rhode Island	G. T. Swarts, Providence	Providence	April	4
S. Carolina	W. M. Lester, Columbia	Columbia	June	—
S. Dakota	H. E. McNutt, Aberdeen	Sioux Falls	July	10
Tennessee*	T. J. Happel, Trenton	Memphis, Nashville, Knoxville,	May	—
Texas	T. T Jackson, San Antonio.	Austin	April	30
Utah*	R. W. Fisher, Salt Lake City.	Salt Lake City.	April	1
Vermont	W Scott Nay, Underhill	Burlington	July	9
Virginia	R. S Martin, Stuart	Lynchburg	June	18
Washington*	C. W. Sharples, Seattle	Seattle	July	2
W. Virginia*	H. A Barbee, Point Pleasant.	Wheeling	April	9
Wisconsin	J. V. Stevens, Jefferson	Madison	July	9
Wyoming	S. B. Miller, Laramie	Cheyenne		

*No reciprocity recognized by these States.

†Applicants should in every case write to the secretary for latest details regarding the examination in any particular State.

Pennsylvania.—A bill has been introduced into the Pennsylvania legislature substituting for the three State Medical Examining Boards one board, composed of nine members, to be appointed by the Governor from lists of qualified members of State medical societies or associations. More rigid examinations will be possible under the new bill, by which the examiners will be empowered to require candidates for license to do laboratory work, demonstrate on the human cadaver, and even practise at the bedside in convenient eleemosynary institutions. Educational requirements are made stricter, and no new license is to be issued unless the candidate has passed a four-year course in a medical school and prior to that has taken a course in some school or college having a four-year course of instruction.

Therapeutic Hints.

Trypsin.—An accident sufficiently serious to warrant its report occurred with a patient, F. J. of B., with carcinoma of the sigmoid and upper rectum, but who was entirely free of cachexia and toxins. An injection of five minims of the drug diluted with 15 minims of specially sterilized distilled water, on December 26, was followed nearly thirty-six hours later by an active delirium, lasting with complete unconsciousness about sixteen hours. During the day of December 28 consciousness began to return, but at night active delirium again appeared, in spite of an injection in the afternoon of amylopsin. Complete recovery occurred only two days later, after full doses of potassic bromide. During the first two nights the patient, a strong man, was with difficulty restrained from injury to himself and others.

C. G. Am Ende, M.D.

Alopecia.—Jessner recommends the following:

℞ Resorcin 2.0
Ac. salicyl..... 2.0
Ac. tannici..... 6.0
Spt. camphoræ..... 20.0
Ol. ricini..... 5.0
Spt. colonien.....q.s. ad. 200.0
Sig.: Apply locally.

℞ Chloral hyd.
Ac. tannici.....āā 6.0
Tr. benz..... 1.0
Ol. ricini..... 5.0
Spt. vini rect.....q.s. ad. 200.0
Sig.: Apply locally.

℞ Ac. tartar..... 10.0
Ac. salicyl..... 1.0
Spt. colonien..... 20.0
Ol. ricini..... 2.0
Spt. vini rect.....q.s. ad. 200.0
Sig.: Apply locally.

Neuralgia.—The following is recommended by Leonard Williams:

℞ Quiniæ hydrochloridi.....gr.v
Acidi hydrobromici diluti.....mxx
Tr. gelsemii.....mx
Aq. chloroformi.....q. s.ad fʒss
M. Sig.: Every twenty minutes till pain ceases. Not more than four doses to be taken.

Sodii biboratis.....ʒj
Potassii nitratis.....ʒss
Tinturæ arnicæ.....ʒij
Aquæ cinnamomi.....q.s. ad. ʒ viij
M. Sig.: Thoroughly rinse mouth three times a day.

℞ Sodii bicarbonatis.
Sodii biboratis.....āā ʒj
Zinci chloridi.....gr vj
Thymol
Menthol .....āā gr. j
Glycerini .....ʒiv
Alcoholis .....ʒij
Aquæ gaultheriæ.....q.s. ad Oj
M. Sig.: Use as a mouth wash.

—Buckley in the *Dental Review.*

Ozena.—Lubet says the treatment of ozena should have for principal object the removal of all crusts from the mucous membrane, as where there are no crusts there is no odor. His idea is to stimulate the nasal secretion so that the crusts become detached of their own accord. To obtain that end he recommends the aspiration through the nose several times a day of a strong boric acid ointment.

℞ Ac. borici.....ʒiv
Menthol .....ʒvi
Petrolati alb.....ʒiss
The boric acid excites the secretion of the membrane, detaching the crusts, and when the patient blows the nose with force they are expelled.

New Instruments.

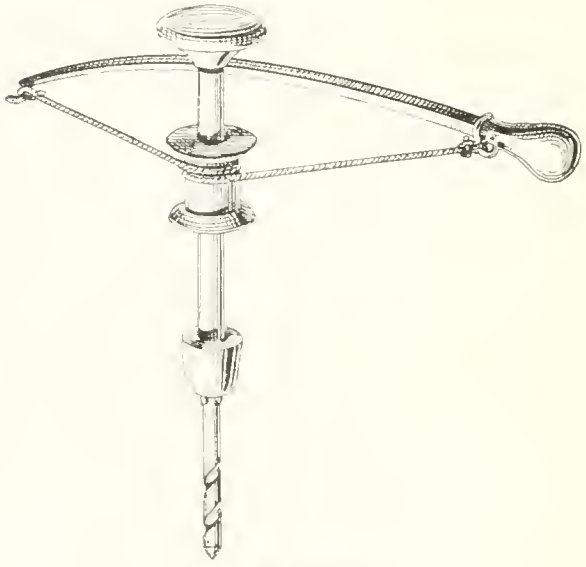
FIDDLE-BOW SURGICAL DRILL.

By FREDERIC GRIFFITH, M.D.

NEW YORK

SURGEON, FELLOW OF THE ACADEMY OF MEDICINE.

A SIMPLE device which I think might be used by surgeons to advantage for the propulsion of drills when wiring bone fragments, or after bone resection work when screw-plates are intended to be used, consists of a fiddle-bow attachment to the shank of the drill chuck. I find the implement, as devised, to be as safe and under as direct control as is the awl when used for similar work, without having the objection of cramping or tiring the surgeon's hands during its use. The bow drill, requires two hands for its manipulation, but its boring capacity is at all times under supervision. Danger, therefore, of the drill "running away," with resulting damage to underlying soft parts or vessels, is not possible, for the number of revolutions depends directly upon the driving power imparted to the bow.



The Fiddle-bow Surgical Drill

As pictured in the cut, the implement consists of a vertical shank, spool, chuck, and handle, with cord and bow. It may be constructed from three-eighths or seven-sixteenths (1 cm.-1.1 cm.) tool steel eight to twelve inches (20 cm.-30 cm.) in length. A revolving handle caps the upper end and a drill chuck the lower. Between, immovably set upon the shank of the implement, is a spool. The bow is of tempered steel ten to fourteen inches (25 to 35 cm.) in length, one-quarter inch (0.6 cm.) square, tapering from the handle into which it is screwed. A hook at the lower extremity and an eye at the upper end afford attachment for the cord. A stout, woven linen curtain cord or similar material may be used as the medium for the transfer of motive power.

All metal parts should be full nickeled. Sterilization is accomplished by boiling. Ordinary twist drills or plain, tapering, double ground boring tips may be used.

49 EAST SIXTY-FOURTH STREET.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious disease reported to the Sanitary Bureau, Health Department, New York City, for the week ending February 9, 1907:

	Cases	Deaths
Tuberculosis Pulmonalis	350	208
Diphtheria	314	57
Measles	195	5
Scarlet Fever	261	12
Smallpox	2	—
Varicella	92	—
Typhoid Fever	61	7
Whooping Cough	65	5
Cerebrospinal Meningitis	10	16
Malarial Fever	..	..
Totals	1350	310

Leukoplasia of the Vulva, the Vagina, and the Uterus.—F. Jayle and X. Bender from their study of this subject conclude that the leukoplasic plaques may occur on the mucosa of the vulva, of the vagina, on the vaginal part of the cervix, and also on the endouterine mucosa when there is found in this location pavement epithelium as a substitute in totality or in part for cylindrical epithelium. Whatever its location may be, the leukoplasia presents the same macroscopic aspect. Histologically it is characterized by three essential features: hyperacanthosis, hyperkeratosis, and an excess of granulation tissue. One of these conditions may be far more striking than the other two in a special case. The variations probably depend more or less upon the age of the lesion. Whatever may be the location of this trouble leukoplasia is frequently the forerunner of cancer.—*La Presse Médicale.*

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine-Hospital Service, during the week ended February 8, 1906.

BRACHIAL NEURALGIA AND ARM PAINS.*

By CHARLES L. DANA, M.D.,

NEW YORK.

Introductory.—The arm and shoulder are supplied by the brachial plexus formed from the last four cervical and first dorsal nerves. This plexus gives off twelve collateral branches (all muscular but the last) and six terminals.

The twelve collaterals give muscular supply and also muscular sensibility to the shoulder muscles, and are nearly all given off from the upper and middle cords of the plexus and fourth, fifth, and sixth cervical roots.

The terminal branches of the brachial plexus which supply cutaneous sensation to the arm and shoulder are the circumflex, radial, internal cutaneous, and musculocutaneous. These all have representation also in the fourth to seventh cervical and arm from the upper part of the plexus, except the internal cutaneous.

Brachial neuralgia is, then, a malady of the upper cords of the brachial plexus and its branches.

It is not my purpose to give a description of the nerves of the arm, as this is to be found in all current text-books. I insert here, however, for the purpose of refreshing the memory:

1. A diagram of the brachial plexus.

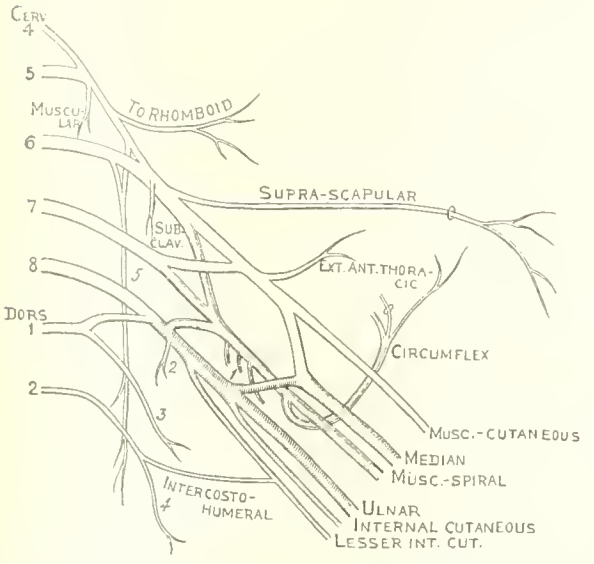

FIG. 1.—The brachial plexus; 1, the subscapular nerves; 2, internal anterior thoracic; 3, first intercostal; 4, second intercostal; 5, posterior thoracic.

2. A diagram showing the sensory areas of the skin of the shoulder and arm (Fig. 2) and showing the relations of the inferior cervical and first dorsal ganglia to the brachial plexus (Fig. 7). Also sectional views of the upper arm and forearm (Figs. 3 and 4).

*Read at a meeting of the Practitioners' Society, December, 1906

It will be seen that the collateral branches of the brachial plexus are all mainly muscular except the last, the internal cutaneous. They are nearly all given off from the fourth, fifth, and sixth cervical roots and the upper cords of the brachial plexus. Hence, pains in the shoulder, except inso-

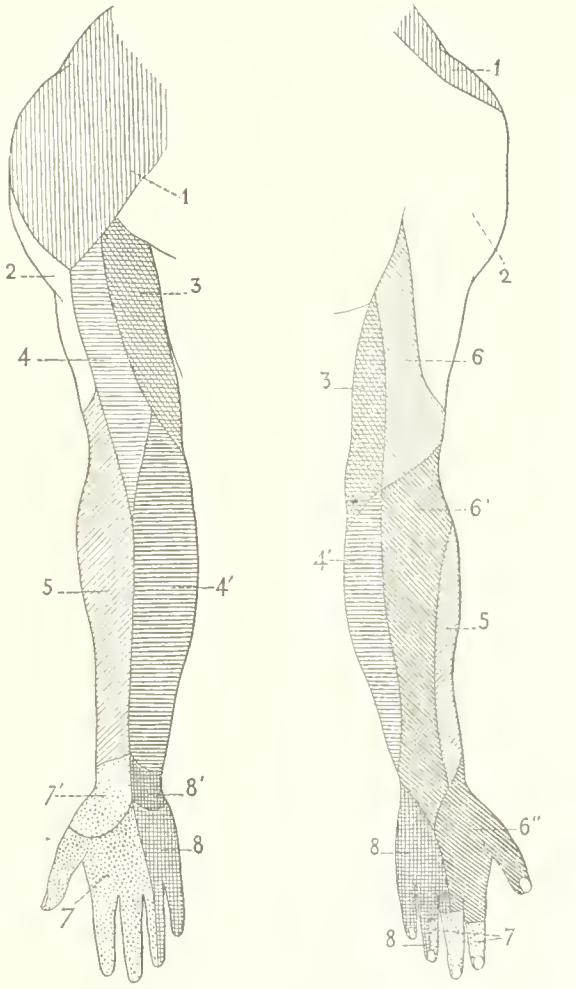

FIG. 2.—Cutaneous distribution of the arm nerves; A, anterior surfacees; B, posterior surface; 1, cervical plexus; 2, circumflex nerve; 3, accessory internal cutaneous; 4, 4,' internal cutaneous; 5, musculocutaneous; 6, 6', 6", musculospiral (radial); 7, 7', median; 8, 8', ulnar.

far as they are muscular and arthritic, are not due to involvement of these collateral nerves.

The terminal nerves of the brachial plexus are sensorymotor and supply cutaneous and muscular sensation to the shoulder as well as arm. They are the circumflex, radial, musculocutaneous, internal cutaneous, median, and ulnar. Now practically, in most neuralgias of the upper extremity, the pains are mostly in the upper arm and shoulder, rarely and secondarily in the forearm and fingers. Hence, it is the circumflex, radial, and musculo-

cutaneous and internal cutaneous that are most involved. These nerves, except the last, come from the fourth to the seventh cervical. Hence, it is mostly the upper and middle cords of the plexus that are most affected. The pains are usually most intense deep in the arm about the shoulder and at the edge of the scapula, as though it were the col-

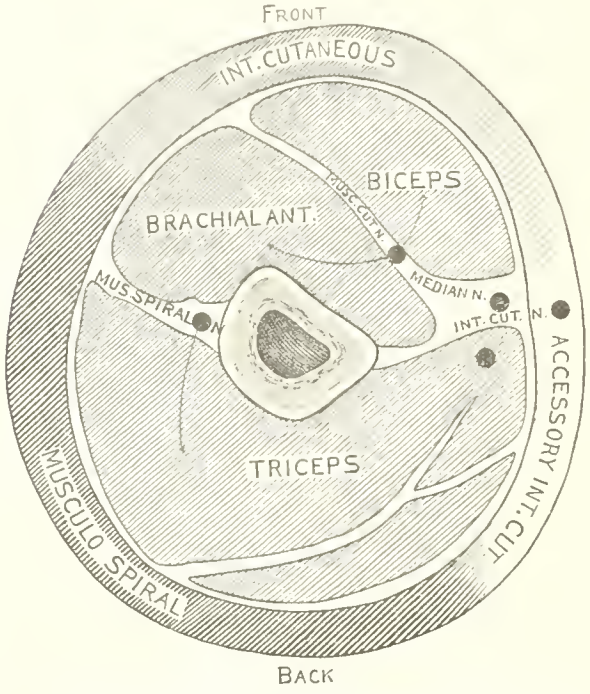

FIG. 3.—Cross-section of the upper arm through the middle of the biceps, showing the position and distribution of the nerves; the lines leading from them show the muscles they supply.

laterals and smaller terminals to the bone joints and deep tissues that were involved. There are few darting pains along the whole nerve, to the fingers, hence, we assume the process is not usually a root neuritis, or irritation, and not a trunk neuritis, but a *terminal neuritis*. It is only late and in severe types that there is evidence of the large trunks being involved. The process means, sometimes, an involvement as much of the cellular and muscular tissues as of the nerve in the ordinary cases. Only in herpes neuritis and in tabetic pains do we get the posterior ganglia affected. At least there are but few exceptions to this rule.

The Nature of Pains About the Shoulder.—Pains just above the shoulder and about the acromion are due to involvement of the supraacromial nerves, which are branches of the fourth cervical.

The deep-seated pains referred to the parts about the joint and in the deltoid, are caused by the circumflex nerve which originates from the fourth, fifth, and sixth cervical, and which is a sensory motor nerve. The superficial circumflex nerve-pains are felt more posteriorly and over the body of the deltoid; there is a painful point where the nerve becomes superficial (Fig. 8).

Pains on the anterior and inner surfaces of the shoulder and upper arm are due to involvement of the intercostohumeral, second dorsal. Shoulder pains, however, generally may be said to be circumflex and supraacromial and to mean involvement of the fibers from the fourth, fifth, and sixth cervical nerve roots.

The circumflex nerve, which thus causes shoulder pains, is given off from the posterior cord of the brachial plexus from which comes the other terminal branch, the radial (musculospiral). Hence, shoulder pains due to this nerve, when severe, radiate down the arm into the fingers, usually the first and second or third, or second and third fingers.

Just above the origin of the circumflex arise the collateral branches to the subscapular and latissimus dorsi; hence, pains or uncomfortable sensations may radiate back into the region of the scapula. Still more frequently pains about the shoulder radiate into the back of the neck along the nerves of the superficial or deep cervical plexus. There is often a localized pain also just above the interscapular space and at about the level of the first and second dorsal vertebræ due to sensory fibers of the posterior branches of the fifth and sixth cervical and seventh cervical, representing the same segments as those of the circumflex and radial (Fig. 8).

Summary.—Shoulder pains, then, mean involvement mainly of the circumflex; if they extend up, the supraacromial nerves; if they extend down to involvement of the radial, and if they extend back to the collateral muscular nerves going to the scapular region.

The Nature of Pains in the Upper Arm.—Pains here are generally associated with pains below in the forearm and hand, and, still more, with shoulder pains. Usually in brachial neuralgia the pain is most dominant in the arm, often in the upper two-thirds, and rather more on the inner side along the biceps, extending to the axilla. The superficial parts on the inner arm here are supplied by the internal musculocutaneous and internal cutaneous nerve. The deeper parts anteriorly by the musculocutaneous, which also has a branch to the periosteum and bone and is the seat of the deeper pains (Fig. 3). These nerves arise from the inner (internal cutaneous and lesser internal cutaneous) and outer cord (musculocutaneous) of the plexus. The musculocutaneous comes from the fourth and fifth cervical, while the internal cutaneous from the first and second dorsal.

Pains in the outer part of the arm, both deep and superficial, come from the radial (fourth to eighth

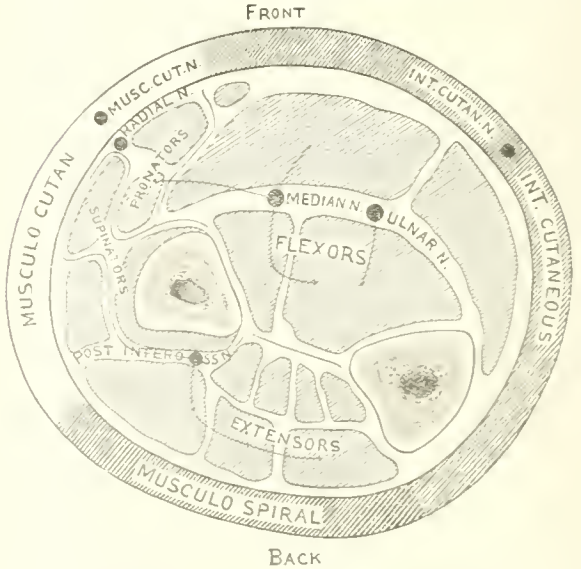

FIG. 4.—Cross-section of the forearm, showing the position and distribution of the nerves.

cervical). Thus when the whole arm is involved nerve fibers from a very long series of spinal segments are under irritation. But generally it is the musculocutaneous and the radial which are the seat of the trouble. These come from the outer and posterior cord of the plexus and the fifth to the eighth cervical roots are represented.

Tender points are felt where the musculocutaneous nerve emerges, where the lesser internal cutaneous and cutaneous branches of the radial emerge.

Upper arm neuralgias are often associated with an interscapular pain a little lower down than the spot found in shoulder pains. It seems to be in the spot supplied by the first and second dorsal (Fig. 8).

Pains in the Forearm and Fingers.—There are rarely any neuralgic or neuritic pains confined to the *forearm* alone. Here we have only the ulnar pains following the course of the ulnar nerve, and very characteristic radial pains following the back of the arm to the fingers, and least frequently median nerve pains. Sometimes the whole hand is involved in neuralgic pain, but this is usually hysterical. The hand and fingers have perethesias and local pains due to local disease, but rarely any true neuralgia.

Heart Pains.—I have been somewhat specially interested in two groups of disorders, namely, the pains in the arms from heart disease, and the pains of brachial neuritis and neuralgia. Of the cardiac arm pains I shall not say very much, however, because the subject has been pretty well studied by others. I have simply made a few observations which I would briefly record now. One of these is that cardiac arm pains are not very prominent factors in the ordinary heart disease of the hospitals, and do not appear so dominant among the laboring classes. Almost always in persons who have a cardiac disease, and who have pains in the arm, there is a decidedly neurotic element. This means, I presume, that the nervous system being more sensitive and unstable, the irritating impulses from the myocardium radiate more freely and arouse disturbances in consciousness more easily. These cardiac arm pains, in my observation, are generally associated with some precordial pain, not infrequently with some pain near the scapula, and also pains on the inner side and middle of the upper arm and middle of the forearm. They rarely extend into the fingers (Fig. 5). Sometimes there is distinctly a pain in

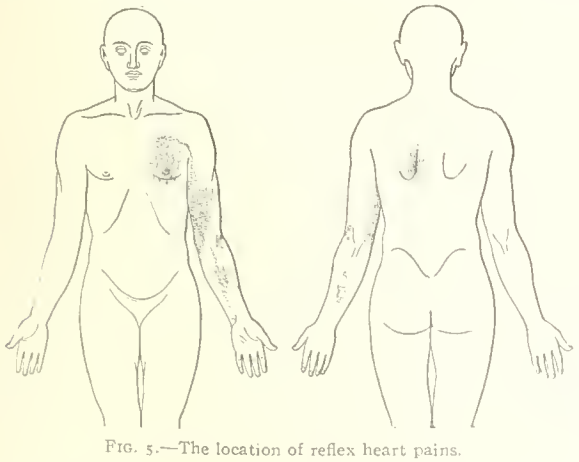

Fig. 5.—The location of reflex heart pains.

the elbows, and in one patient of mine, with a pronounced cardiac disorder, whenever the heart became a little overstrained, there were pronounced pains in both elbows. We sometimes note, also, pain in the right arm instead of the left. I have made a diagram on which I have plotted out the places in which pains were felt in a dozen of my cases. I am unable to say that there is anything so distinctly characteristic in the location or character of the pain that one could by it alone say that it was *cardiac*, except, perhaps, that there is generally a feeling that the pain comes from the left side and runs from there into the arm. The cause of this reflex disturbance is generally attributed to the fact that the third or lower cardiac ganglion of the cervical sympathetic sends fibers which communicate with the first dorsal nerve, which nerve supplies the inner side of the arm (Fig. 7).

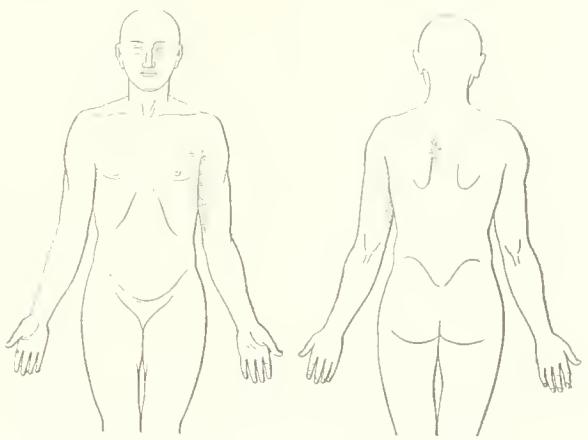

Fig. 6.—Pain under the shoulder, or the inner side of the arm, and between the scapulæ, due to a lesion of the posterior second dorsal ganglion, with herpes; this is like certain heart pains.

Brachial Neuralgia and Neuritis.—*Definition and Frequency.*—Neuralgia of the brachial plexus is a disease characterized by severe pains centering in the upper arm and usually involving the whole upper extremity and shoulder; it runs a course of several months and is due to irritation or inflammation of the trunks of the brachial plexus and its roots of origin. This irritation does not usually reach the degree of neuritis, and the disease does not show the paralysis and atrophy, anesthesia and vasomotor symptoms of neuritis as a rule. This

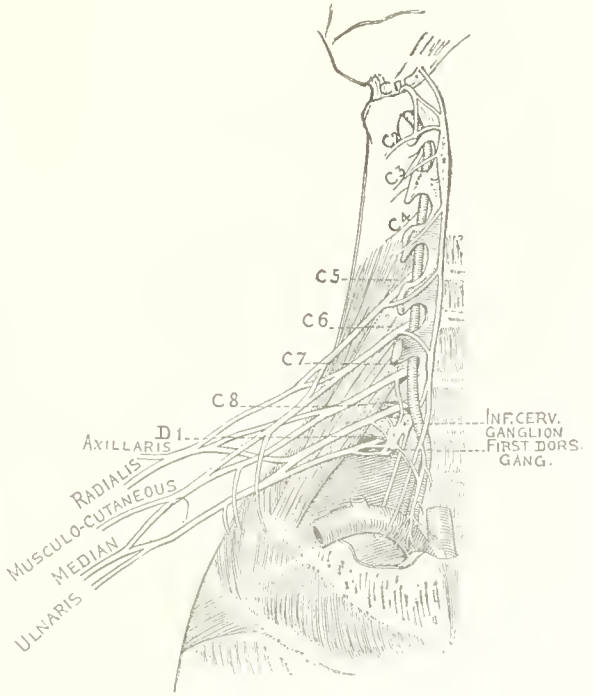

Fig. 7.—Showing the relation of the third cervical and first thoracic ganglion (blended together) with the brachial flexus

form of neuralgia, excluding the cases of traumatic neuritis, is now by no means a rare disease. Among the neuralgias brought to the attention of the neurologist it ranks third, coming after the facial neuralgias and closely following in frequency the sciaticas. In the past, however, brachialgia has re-

ceived but scant attention from the writers, both on general medicine and in special text-books. Even in works devoted especially to the study of neuralgia this characteristic modern affection, as it seems to me, is not portrayed, as it is seen at least by physicians and neurologists in this country.

In Bernhardt's comparatively recent article (Nothnagel's Special Pathology) the subject is somewhat extensively dealt with; Bernhardt finds that among 685 cases of neuralgia there were 108 of the brachial type. But the neuralgias seen in Berlin by this author are apparently those due largely to trauma and to occupations which lead to exposure of the arms, such as those of firemen and washerwomen, etc. His cases are apparently often forms of traumatic neuritis and do not all belong to the class which I propose to describe now.

In support of the point just referred to that the typical brachial neuralgias have increased in frequency in the last two decades, I can only now bring forward my own statistics and experience. In 1888 I made a collection of reports of 453 cases of neuralgia and found that among them there were of brachial neuralgias only eight, or about two per cent. These figures, to be sure, were very largely obtained from dispensary and hospital statistics, but they do not vary very greatly from other figures from a similar class of material. Thus, Eulenberg, in his statistics, places brachial neuralgia fifth in a list of six different types; Lechnit puts brachial neuralgia fourth in a list of five types; Conrads places it fourth in a list of eight types. In general, writers seem inclined to make brachial neuralgias rank in frequency after sciatica, the trigeminal neuralgias, the intercostal neuralgias, and the occipital neuralgias.

Looking over the records of my private cases I find that among 197 cases of neuralgia the different forms are in the following order of frequency:

Tic douloureux	44 cases
Sciaticas	40 "
Brachial neuralgias	41 "
Other forms	73 "

These other types include a good many of the inner types of trigeminal, occipital, and spinal neuralgias.

There have, of course, always been a great many arm pains of various types, and these have added to the apparent statistical superiority of the brachial neuralgias in the tabulated lists of different types; but I am particularly insistent upon the point that it is the typical brachial plexus neuralgia which is a prominent, dominant, and probably more frequent clinical disorder now than it used to be.

In my private history books I find that I have a list of 79 cases of arm pains of various types. These I have classified as follows, and it shows that, leaving aside all symptomatic troubles and all occupation neuroses and local troubles, there is still a large percentage of pure brachial neuralgias:

Total cases of arm pains	79
Total brachial neuralgias	41
Arm pains associated with distinct neuritis	15
Occupation neuroses with dominant arm pains	16
Hysterical arm pains	4
Palmar, digital, and hand pains due to local or reflex causes	6

These do not include arm pains due to tumors, aneurysm, or cardiac disease, or tabes dorsalis.

Brachial neuralgia or neuritis is thus by no means a rare disease. Its frequency, at least in this city, is undoubted. There is, I am assured by a patient, a distinctly neurotic face, characterized by certain expressions of appreciative elation when the word is mentioned.

I have been struck with the fact that brachial neuralgia is seen more frequently in women, and in women of the leisure classes. They have not perhaps led idle lives, but they have never used their arms in domestic or maternal work as the woman in general is obliged to do, and they have generally been of a nervous organization, *i.e.* of a well-evolved type, and have been good livers. So that I have ventured to advance, with some reservations, a theory, if you will, that the arms of these modern women are becoming quasi-vestigial, like the appendix, the jejunum, and the last molar tooth. That they will always have some use I do not doubt, and will be sufficient even in the most advanced period of our civilization for the purposes of feeding and the actual uses of the toilet and simple coordinative efforts; but that they are becoming rather more weak and of less importance in the economy of woman seems to be probable.

The arm bones go with the weakening members, and it has been shown by Ravenel that the cervico-spinal cord is relatively smaller in women than in men, though on the whole the spinal cord of women is relatively larger in proportion to the brain and the lumbar cord is larger proportionately than that of man.

The statements of Ravenel are confirmed by those of Köllicker and Stilling. These authors find, for example, that the total square area of the motor roots of the cervical nerves, from the fifth to the eighth, is about the same in men and women. While the total area of the posterior roots is one-half as large in women as in men, the total area of both roots is about twenty per cent. smaller in women than in men. This would indicate that the sensory supply of the arm in women was only one-half as great as that in men, and it might be supposed that with this inadequate nerve supply, strains on the arm would call out trouble more quickly. On the other hand, the area of the last two lumbar and first two sacral nerves is much larger in women than in men, for both the anterior and posterior roots.*

Etiology.—Brachial neuralgia occurs oftenest in persons in middle life, ranging from thirty-five to fifty. When it occurs in young people it is (like the other neuralgias) more often of the hysterical type, or at least associated with that class who are neurotic and oversensitive. Besides having an hereditary neurotic history as the underlying tendency, there is almost always a history of severe emotional strain, loss of friends, sickness in the family, or worry over complications of domestic life. Sometimes in addition there is some physical

*Proportionate Length of

	Cervical Cord.	Dorsal.	Lumbar.
In man	22.4%	47.1%	30.5%
In woman	21.5%	46.6%	31.9%

—Ravenel, in "Merkel's Anatomy."

Area of Cervical Nerves from C. V. to C. VIII.	Male.	Female.
Ventral (anterior) roots	16.38 mm.²	16.02 mm.²
Dorsal (posterior) roots	40.04 mm.²	21.30 mm.²
Total arm	56.42	47.32

Area of Lumbosacral Nerves from L. IV. to S. II.	Male.	Female.
Ventral	14.36	17.46
Dorsal	31.04	33.24
	45.40	50.70

Thus, woman has only one-half as many sensory nerve fibers in her arm plexus as man, but has rather more motor and sensory fibers in the lumbosacral nerves. But she rarely has sciatica.

injury or some acute sickness. In two cases I have seen it follow profuse hemorrhages. In some cases it is due to inordinate use of the arms in simple manual work, like embroidery or knitting; but this seems to me rather unusual. A mild form of brachial neuralgia occurs as the result of carrying a heavy skirt, and it is not unlikely that this kind of work (skirt carrying) and the use of the arms in dressing the hair brings on neuralgia in a great many predisposed cases.

In my experience, then, neuralgias are seen oftener in the better classes than in dispensary or hospital patients. They occur, according to my observation, oftener in women than in men in the proportion of about three to one. This is contrary to most statistics, because, as I believe, these statistics include many frankly traumatic and surgical cases. There is often a predisposing neurotic or rheumatic taint, and sometimes perhaps an autotoxemia. The brachial neuralgia of tabes dorsalis and organic disease is not included in this discussion. In fine the etiology of brachial neuralgia has always one or more of three factors: Neurotic constitution, exhaustion from occupation or trauma, and metabolic (rheumatic) irritation.

Pathology.—Brachial neuritis proper, nontraumatic, in which there are objective evidences of nerve degeneration, is probably only a severer and more profound type of brachialgia. The common form, then, of the arm pain is usually designated as a neuralgia, though there is probably some low grade of inflammatory process in the sheaths if the nerves; and if it is desired to use the term "neuritis," I do not know that serious objection could be made. So far as I am aware, no post-mortem examinations have been made of the nerves of persons suffering from this condition. If we may infer concerning it by analogy, from conditions seen in sciatica, the existence of perineuritic irritation, and perhaps slight exudate, is probable. It seems to me that sometimes the inflammation is not so much in the nerve sheaths as in the muscular and connective tissues about it, and that there is a myositis as well as secondary neuritis. I shall assume that in using the word "brachial neuralgia" I include both the neuralgias, with no objective symptoms, and the distinctly neuritic cases, of nonsurgical origin.

The symptoms of brachial neuralgia are somewhat as follows:

The onset is rather sudden, but there may be severe preliminary aching in the arm for a few days, and sometimes there are short preliminary or abortive attacks. Usually, however, the patient wakes at night or notices in the morning a distinct and severe pain involving the upper arm and shoulder, or perhaps the whole arm. The pain usually is most acute, however, on the inner and front side of the arm and in the back between the shoulders. It is very intense and runs down the forearm and into the fingers, involving sometimes the whole hand, but usually only the first, second, and third fingers. It is not a darting, shooting pain, but seems to be one that is general and diffuse, involving for a time the whole arm with a pain of paralyzing intensity. The pains exacerbate, coming on usually at night more severely, or more in the morning, and always more after exertion. Movement makes the suffering worse; but the arm can be handled gently without much pain. Some suffering is present nearly all the time, often robbing the patient of sleep; but it may let up for a few hours during the day and then comes back again with paroxysms of great intensity lasting for one or two hours.

Many patients try at first to work off the pain by exercise, thinking it a form of rheumatism, or they get a masseur who rubs the arm, and, as a rule, makes it worse. There are, however, at times, attacks that are short and abortive. I have known some to last three or four days, and in these instances the massage or the doctor get the credit for a therapeutic triumph entirely undeserved. Usually the pains progress and continue for two or three weeks until the trouble is pretty firmly established, continuing then for two or three months.

When the pain first comes on there are no objective changes in the arm. It looks normal and is simply tender and sore to the touch. Later the arm becomes a little swollen and the fingers somewhat edematous, and there is slight flabbiness of the tissues, showing vasomotor change.

In the typical neuralgias there is rarely much more than this. If it is a genuine neuritis, of course atrophies and paralyses gradually develop, but it is not of this type of the trouble that I speak. In brachial neuralgias proper the changes in the arm are only slight—the grip of the hand becomes weak, the elbow jerk is a little exaggerated at first, muscular irritability is increased and then diminished, and there is no anesthesia.

Examination shows points of tenderness along the course of the nerve on the inner side of the arm at the elbow and over the deltoid. There is also a point of tenderness between the scapulæ about at the level of the second or third dorsal vertebra. This is very painful and is characteristic. Stretching out the arm and drawing upon the brachial plexus brings out pain, just as it does in the extension of the hip in sciatica. Later there is also weakness of response to the elbow jerk, just as in the tendo Achillis in the later stages of sciatica. The tender points that one finds in brachial neuralgia are by no means always identical with the tender points of Valleix. They vary somewhat and only correspond in a general way to the distribution of the cutaneous nerves (Fig. 8).

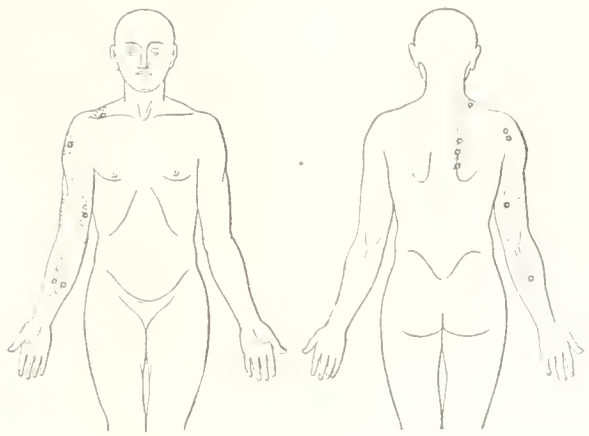

Fig. 8.—The pains and painful points of brachialgia.

It will be found, as we watch the neuralgias from the back of the neck down to the hand, that pains in these different segments are associated with painful points along the course of the spine. For example: In occipital neuralgia there will be a well marked tender point close up to the base of the skull over the second or third cervical spines. With a cervicobrachial neuralgia the point moves down to near the first or second dorsal. With a brachial neuralgia the spinal tender point moves to the neighborhood of the third or fourth dorsal. These spinal tender points are quite characteristic of neuralgias of

the upper cervical plexus, and the collaterals of the brachial plexus.

Diagnosis.—In the chronic and less severe types of arm pain one may be easily misled in diagnosis. The first and obvious name given to an arm pain is "rheumatism." The patient is always treated first for this.

It is safe to say that arm pains are never purely rheumatic, unless there is found some objective evidence of myositis, arthritis, or periarthritis. The most difficult thing is to distinguish between real neuritis of high grade and neuralgia. Neuritis has become a popular diagnosis nowadays, and patients talk very glibly about the term. It seems as a neurological diagnosis, to please the laity, as having a certain distinction that doesn't belong to plain rheumatism or neuralgia. It is, in fine, in a diagnosis *à la mode*. But a neuritis cannot be recognized except by some objective signs. There must be pain and also tenderness along the nerve; there must be definite areas of hyperesthesia or anesthesia, muscular weakness, and perhaps atrophy and electrical changes. There must be some of these symptoms in an inflammatory process that lasts three to six months.

In about half of my cases of brachial pains no such objective symptoms were present. The condition is not one of actual inflammation, but of exhaustion, and in the majority of cases brachial neuralgia is an exhaustion neurosis with some rheumatic or metabolic irritation of the nerves in addition.

In brachial neuralgia the rheumatic poison is nearest to being the common irritant, but antirheumatic medicines rarely affect the process radically. Gout does not cause a general arm neuralgia, but may attack individual nerves, causing special forms of gouty neuritis. Neuralgia of the arm, like lumbago and other rheumatic symptoms, sometimes precedes an attack of melancholia.

When we find a herpes along with arm pain we know that we have an inflammation of the spinal ganglion and secondary neuritis and that the process is due to an infection.

The question arises, therefore, whether some of the other cases of brachial neuralgia are not due to infection, attacking the trunks instead of the ganglia of the nerves. I am inclined to think that the infection theory will sometimes answer. But the trouble is too often the very evident result of overuse of arms, of nervous and mental depression, and its course is not acute, like that of herpes-neuritis.

Treatment.—I have not found treatment of brachial neuralgia of any avail without rest. This must be secured by a sling, and, if necessary, by splints. In a good proportion of cases some relief is gotten by the salicylates, especially aspirin, but they must be given in very large doses, just as for acute rheumatism.

Neither massage nor hot baths should be given at first. But after two or three weeks hot applications of *mud* or flannel can be used. The patient must understand that, as a rule, it takes ten or twelve treatments to accomplish results.

After a course of salicylates, tonics can be given. I do not know any drug that is of any special value, unless it is strychnine, in massive doses, and of its utility, I am sure, in chronic cases. Some patients rush off to Hot Springs at Virginia or elsewhere when they find their neuritis coming on. The treatment here is not abortive, however, and sometimes not especially helpful in the acute cases. The trouble is that at the beginning patients need most of everything rest, and this is not obtained satisfactorily at our American bath resorts or by a trip to Europe.

Arm pains, which once were due to neuritic conditions, sometimes become habit pains; the patient has a "constitutional armache," just as some have constitutional headache. The best and only treatment for these patients is to ignore the trouble absolutely. When the pains are rather chronic, *i.e.* after four to six weeks, massage and electricity do some good. The patient gets well anyway in three to six months as a rule.

The disease may recur, but this is rather rare, and only in about ten per cent. of my cases.

It is rarely double, and when so is invariably an exhaustion neuralgia, rather than a pure neuritis.

THE TREATMENT OF ACUTE DIFFUSE PERITONITIS.*

By RICHARD DOUGLAS, M.D.

NASHVILLE, TENN.

In presenting my views upon acute diffuse peritonitis, I am merely publicly accepting the conclusions that are forced upon us by the combined work of the bacteriologists and the surgeon. It will not appear that I have anything new to relate; no theories to expound; no ingenious technique to elaborate. Indeed, I question much if there is anything in this subject unknown or omitted by the multitude of scribblers who have oppressed the press.

Some old fellow once said: "To know a thing and not to express it is all one as if he knew it not." This scarcely applies to me, for I do not know my subject, and I feel the irritation of deficiency, and "one must needs scratch where it itches."

To the subject of acute peritonitis I have directed the closest study. Many years ago I reported to the Southern Surgical Association in Charleston a series of eight cases of general peritonitis treated by operation; six recoveries, two deaths. I received the applause of the fellows, and believed that I had mastered the problem which was the awe of all abdominal surgeons. I was young then and a professor, and did not hesitate to draw conclusions and dogmatically emphasize them. Encouraged by this success I some years later, in a presidential address before the same association, again elaborately considered the subject of peritonitis. My paper seemed to merit the approbation of the fellows, and upon motion of Dr. Howard Kelly was ordered printed in pamphlet form for distribution. I now felt that I knew it all: that this immense lymph sac with its physiology and pathogeny was an open book to me.

After this my opportunities for observation became more numerous: my mortality list remained consistently high; I grew older, more conservative in judgment, surrendered my professorship and lost with it that egoism that beclouded my studies and endangered my patrons. I recognized that my results were no better than many, and not so good as some. I continued to open tense bellies, pus gushed forth. I measured my skill and achievements by the quantity of pus found; yet my mortalities came unexpected and with frightful frequency from another class of cases.

The acutely infected peritoneum became a chamber of horrors to me, and, though my studies were considered exhaustive by some, they were, *ab initio*,

*An address delivered before the Nashville Academy of Medicine and Surgery, January 1, 1907.

faulty. I did not even know the nomenclature of the disease; I spoke of curing general peritonitis when neither hand nor eye had reached above the umbilicus. The published reports of my confrères excited my jealousy and wonderment.

I have not impugned their integrity, yet I am frank to confess that there is something in the environment of the operating room that distorts the vision and exalts to a superlative degree the pathological findings. It is the unconscious yielding of weak human nature to exaggerate difficulties that there may be all the greater praise for the achievement of overcoming them.

Chemical and mechanical peritonitis were in those days considered possibilities, and every case was general peritonitis that was not a distinctly localized abscess. Surgeons were not familiar with or had not accepted the teaching of Senn and German authorities. Peritoneal sepsis was hinted at, but not comprehended. Empyema peritonei was incised; quarts of pus evacuated, flooding the operating arena, the surgeon floundering in pus and ignorance, raised aloft his knife, exclaimed, like Monte Christo, "The world is mine." He had done only scavenger work; the battle was waged before he came upon the field. Upon the first approach of the enemy, leucocytes were hurried to the scene of action; phagocytes occupied the skirmish line, while the vital fortress was held by the opsonins.

In my studies of the various surgical diseases of the abdomen I still tried to master the unsolved problem of peritonitis. This labor brought its reward; my mortality list fell from eighty per cent. to perhaps sixty per cent. Prognosis before operation became more guarded, and, what is more to the point, it was appreciated that the ultimate issue of the case does not rest upon the manifest reaction in the peritoneum to infection found at operation; indeed, quite the reverse has been true.

I reached the conclusion that peritonitis is not always the same disease; that many factors, chiefly bacteriological, determined its onset, course, and ultimate termination. Manifestly then, there is no one treatment for peritonitis; no method applicable alike to all cases; no one man's technique that I am willing blindly to accept; no teaching so comprehensive, so universally applicable that we should follow it to the rejection of all others.

I can ask no greater boon than that I may enjoy that discriminating understanding which will guide me to select and apply that treatment which meets the special indications. Such judgment must rest upon an intimate knowledge of the pathogenesis of peritonitis, the behavior, habits, and virulence of all organisms concerned, and upon nature's combative methods; therefore, it must be clearly understood that the surgeon is nature's auxiliary, and I hope to show that rude, aggressive, self-assertiveness, sometimes called thoroughness or radical surgery, hopelessly overturns nature's defence.

When the bacteriologist, after his apparently fruitless but unremitting labor, presents a conclusion following his investigations which does not run counter to clinical observations, but strengthens and sustains them, if we practical workers reject his findings, we discredit science and confess ourselves to be mere votaries of the hippocratic school of medicine which promulgated theoretical dogmas.

We cannot attribute specific action upon the peritoneum to special bacteria, but it can be safely stated that that virulent form of peritonitis in which there is but little serous and no fibrinous exudate, is due to the streptococcus infection; that in the great majority of cases of spreading peritonitis the colon bacillus is the active germ.

I would overshoot myself if I attempted to enter into the bacteriology of peritonitis. We all know that the *Streptococcus pyogenes* and the *Bacillus pyocyaneus* and the pneumococcus produce rapidly fatal results when inoculated upon the peritoneum. Their baneful effect appears to be in the rapid disintegration of the leucocytes.

I shall merely touch upon a new field of thought in connection with the bacteriology of peritonitis, that of induced immunity or the increased resisting power of the peritoneum.

Many experimenters have shown that the resisting power of the peritoneum can be artificially increased, and I quote from Dudgeon and Sargent what has been done along this line: "Issaeff, in 1894, was the first to show that various sterile solutions previously injected into the peritoneal cavity of guinea-pigs could render that membrane more or less refractory to infection with certain pathogenic organisms. In the following year Melsome and Cobbett, working with cultures of 'streptococci,' showed that an immunity could be produced by successive minute inoculations. Durham obtained similar results in rabbits from preliminary infection of sterile fluids. More recently, Salieri and Miyake, working under Professor von Mikulicz, have confirmed these observations and succeeded in producing an artificial immunity in animals by preliminary intraperitoneal injections of sterile saline solution, nucleic acid, and other substances. The protection thus afforded is, as Durham pointed out, due in large measure, at any rate, to the appearance in the peritoneal exudate of certain phagocytic cells. It is a general, not a specific immunity against peritoneal infection. Sargent and Dudgeon believe that this artificial protection has its counterpart in the natural events of peritonitis. Their reasoning is supported by systematic examination of the peritoneum in two hundred and seventy cases operated upon at St. Thomas' Hospital, London.

The organism that is first to make its appearance in the peritoneal cavity under abnormal conditions is the *Staphylococcus albus*. As a general rule it is found on the peritoneal surface at a distance from the focus of greatest disturbance, and it is usually associated with a number of phagocytes at the site of primary infection; the staphylococcus has been displaced by more active and virulent germs.

The staphylococcus is the germ that is present in most cases of intestinal obstruction, tumors with twisted pedicles, and strangulated hernia. If the obstruction or cause is relieved, this germ does not produce a fatal peritonitis; it rarely causes suppuration of the parietal wound. The effect that it does produce is the advent of a number of phagocytic cells.

Now why the staphylococcus appears first upon the scene, we do not know; but it provokes a clear fluid exudate which soon becomes turbid with leucocytes; and, as Sargent significantly remarks: "The more turbid it is, the more it appears to the surgeon that it is something to be washed away."

Later in the stage of inflammation the colon bacillus comes upon the scene. It is on the start, so to speak, which the white staphylococcus had, and the ability of the individual to respond to the call by supplying phagocytic cells that the prognosis to a large extent depends. The proof of this last statement is that in the simultaneous inoculation of *Staphylococcus albus* and colon bacillus there is little or no protective action exerted; that is, there is no phagocytosis and a quickly spreading fatal peritonitis supervenes.

A second important part played by the *Staphylococcus albus* is that it assists in the formation of

adhesions Cultures taken from coagulated fibrinous exudate show the constant presence of this organism. The agglutination of the intestine by fibrinous exudate mechanically resists spreading peritoneal infection. The coagulation of exudate fibrin deposit upon the peritoneum, limits the absorption of toxic material and at the same time prevents egress of organisms from the intestine. It has, therefore, a protective function.

If I grasp the idea correctly, it is now established, chiefly by the work of Dudgeon and Sargent, that the *Staphylococcus albus* and perhaps other microorganisms, when inoculated upon the peritoneum have the effect of causing a copious serous and fibrinous exudate, and invite an abundant migration of lymphocytes into the cavity; and I may add, this serous exudate contains the opsonins, that element in the blood plasma which renders the bacteria available for phagocytosis.

A patient's resistance to an infection then, depends upon the leucocytic reaction consequent upon the infection and his opsonic index. Another element materially affecting the prognosis is the extent of the area over which microorganisms are diffused; for, says J. Walter Vaughan, "given the same organisms capable of forming the same toxin and the same amount of toxin, the severity of the disease will depend upon the area involved."

Some of you may perhaps be familiar with Vaughan's culture experiments in large glass tanks. The inner surface is lined with a coat of agar agar. Over this is poured a very small amount of bouillon culture of microorganisms. It is almost inconceivable the abundant harvest coming therefrom. We know that germs confined in a test tube soon lose their virulence.

The peritoneum is likened to a Vaughan tank; it is a sterile chamber under ordinary conditions, but when danger threatens in the form of perforation from appendicitis or other cause, it attempts to protect itself by the formation of adhesions. This limits the area wherein germs can grow. The circumscribed part of the cavity is converted into a test tube or local abscess, if you please. The microorganisms lose their virulence, and the area of absorption is limited. These experiments have a practical value to which I will again refer in the discussion of irrigation.

My untrained mind does not grasp the technical conclusions of the bacteriologists further than stated above, although I have read with great care and profit the excellent lectures of Dudgeon and Sargent upon the Bacteriology of Peritonitis. It is not yet possible to make a bacteriological classification of peritonitis. For precision and clearness I return to the definite subject in hand, acute diffuse peritonitis, defined as a spreading infection of the peritoneum which results from perforation of the appendix or other viscus. The inflammation is established and progressive without definite limitation: there is evidence of inflammatory exudate, extensive redness of the peritoneum, and intestinal paralysis.

Blake further subdivides diffuse peritonitis into spreading and general. In spreading peritonitis, parts of the peritoneum can be shown to be free from infection. By general, or a better term would be universal peritonitis, we mean that form in which no part, possibly excepting the lesser sac, is uninvolved.

To this I might add acute peritoneal sepsis or the peracute peritonitis of Mikulicz. This is the fulminating peritonitis which proves fatal from septic intoxication or from so-called shock before there is any real peritoneal exudate, but in which there is more or less intestinal paralysis. Bacteria, usually streptococci, are found in the bowel wall and in the omentum and in the lymphatics. This severe form of infection, so frequently fatal in a few hours, is mentioned merely to eliminate it from the discussion and to avoid confusion.

Pardon this preliminary wandering and I will at once descend to the particulars of my subject, "The Treatment of Acute, Diffuse Peritonitis."

Opium and sulphate of magnesium have had their day. To discuss them here would be a tedious recital of medical history.

After Tate came the years of vigorous surgery. The natural reaction from this was the Ochsner waiting policy. He states that no matter in what stage diffuse peritonitis comes into the hands of the surgeon, if the stomach is washed out and nothing administered by the mouth, nourishment and fluid supplied by rectal injections, in the vast majority of cases the process will become walled off, the acute symptoms will subside, and the patient can safely be operated upon at a later date. His treatment is especially directed to that form of perforative peritonitis following appendicitis.

Ochsner adduces statistics to support his position. My personal experience with this method has been peculiarly unfortunate. In every instance in which I have followed it, and I have judiciously selected my cases, I have lost not only the patient, but the confidence of the attending physician; and so I emphatically declare I will have nothing more to do with it. And yet I do not contemn it, for it is a method employed by some of the most fortunate, successful, and ablest surgeons. It is especially popular, however, with the statistic builder; it is an avenue by which the not over-conscientious surgeon may escape from a predicament and preserve his record and leave the internist with the bag to hold to answer the accusation that the surgeon was called too late.

I do not charge that this is done, but it appears to me as a possible expediency; but the following argument I *know* is made: "Why should I operate upon this desperately ill man? The chances are against recovery from operation, and if he dies it will discredit surgery and cause others yet to be taken ill to decline operation." So it is argued, the science of surgery is discredited, and humanity indirectly harmed. This is not the occasion to elaborate further my conception of the surgeon's duty. Suffice it to say that in private work his highest obligation is to his individual patient, regardless of how it may react either upon him, you, or the community. A public official, say a sanitary officer, occupies an entirely different relation toward his patient. If needs be, for the protection of the community, he would be justified in shooting down a pestilential individual.

The Ochsner treatment is popular with some medical men, usually with the class that have a quondam affection for the old opium treatment or the more recent calomel and salts line of management. In many cases, as is well known, the inflammation will abate for the time, and he will score a temporary success. The value of the Ochsner treatment is "that it permits nature to do her best, and that is all there is in it." It has not maintained its popularity.

Simon Young, of Valparaiso, Indiana, addressed this question to twenty-five of the leading surgeons in the United States: "Do you make it a rule to operate upon acute diffuse peritonitis?" Seventeen

replied yes, seven gave affirmative replies with qualifications, one avoided operation if possible.

You see that it is impossible to deal with the subject of diffuse peritonitis without referring to appendicitis, as the peritoneal infection so commonly originates from appendicitis. "This waiting policy has been practised in the city hospitals of Boston with an occasional success, but more frequently ultimate operation has had to be done under less favorable circumstances." (Lund.)

At Roosevelt Hospital, in New York, immediate operation is practised; and one of its representative surgeons so expresses himself upon this point: "The advocates of the Ochsner treatment by rest will concede that the patient will be better off with the appendix out if it can be done without operation. We have simply to weigh the dangers of toxemia and shock of operation against the danger of continued infection, both systemic and peritoneal, from the appendix itself or the escape of its contents." (Blake.) John B. Murphy, with his unparalleled success in thirty-eight cases with one death, has this to say of the Ochsner treatment: "It is the effort of the unconquered, nine-lived procrastinator."

See what another surgeon says: "The diagnosis of perforation, if we are on our guard, is easy; and, although it may be difficult to say which organ is affected, this does not make any difference. The vital consideration is that it has happened, and immediate operation must be performed." These are the words of William J. Mayo, and I offer them as conclusive evidence against the Ochsner treatment; yet I am aware that this surgeon advocates and practises delay in certain stages of appendicitis, and I am at a loss to comprehend a rule that applies to one portion of the abdomen and not to the other. The limited absorbing capacity of the lower zone does not give the claimed immunity; and the infectious matter escaping from the appendix may be as abundant as from a perforation in other viscera.

In considering the surgical management of acute diffuse peritonitis, I shall omit many details that would prove irksome to the surgeons in the audience, and uninteresting to the medical men, and enter at once upon the discussion of certain points that are under dispute hoping that I may bring out of much confusion some system, some intelligent application of the means at our command.

I would eradicate, if possible, from the literature of this subject, that empiricism which seems to possess it. Special steps in the technique are observed; special methods are employed, and why? Because, forsooth, some surgeon has reported a small series of cases all successful; therefore, his method must be good. Let us ask ourselves the question before accepting the method of treatment, why is it preferred? What is its foundation? But above all, what is the surgeon's capacity and inclination for intelligent observation? I grant you such inquisitiveness may lead us into embarrassment; yet I contend it is a search after the truth, and upon this line I will now briefly pursue this subject.

All patients with tense bellies and that are vomiting, should have gastric lavage before taking the anesthetic. General anesthesia is preferred to local. If the patient is too ill to take ether, then I hesitate to operate upon him. The incision should be over the supposed site of infection and should be free so as to permit ready access, for the indication is to remove, close, or segregate the source of infection. If there is great accumulation of fluid, the force of intraabdominal pressure will cause it to spurt from the cavity when the peritoneum is nicked, and we must avoid extrusion of coils of intestine from the wound. Although we find free fluid and distended intestine under our incision, we must assume that peritonitis is limited, and employ gauze to cofferdam the field of operation. The gauze so packed about has a three-fold effect; it prevents prolapse of the intestines, avoids needless handling of those viscera, and while in place absorbs what fluid there may be, preventing its dissemination, soiling clean areas should we accidentally break up an adhesion. If no adhesions are found, the gauze rapidly takes up free fluid from the general cavity. This protective packing should remain in place until the local focus of infection is dealt with.

Finding a great quantity of purulent matter and no manifest adhesions, we come to the question of its removal. It has been uppermost in the minds of surgeons that the first step after opening the abdomen and removing the source of infection, is to cleanse the peritoneum of the exudate or other foreign material.

Until very recently copious irrigation has been the method of treatment. Now, in this country, following the teaching of Murphy, it is held to be a grave error of technique to wash out the peritoneal cavity. How often has it been expressed of late that irrigation is wrong because it disseminates septic matter throughout the peritoneum. This is not all; just a word to refreshen ourselves of the facts in bacteriology. In all severe cases of perforation peritonitis the colon bacillus or some more virulent germ is present at the focus of infection, while in remote portions of the abdomen the *Staphylococcus albus* may be the only microorganism found; indeed, cultures from remote regions may be sterile.

There can be no doubt in these cases that if we flood the abdomen we carry from the intensely septic field a watery solution of colon bacillus, and at the same time we wash out the phagocytes which are Nature's only soldiers of defence. We practically make of the general peritoneal cavity a Vaughan tank, and in a short while there is a universal growth all over the peritoneum of microorganisms, and sufficient toxines are eliminated to carry out patient away.

I hold that experiments of bacteriologists have demonstrated this fact, and now for the clinical substantiation of it. Between the years 1899 and 1903, there were operated upon at St. Thomas' Hospital, London, 119 cases of appendicitis with diffuse peritonitis; 100 were treated by washing the peritoneum with large quantities of sterile water or normal saline solution. Of these 80 died. The remaining 19 were treated locally; of these 10 died, that is, the immediate neighborhood of the appendix was gently sponged out, while the upper part of the peritoneal cavity was not interfered with. The mortality then after general lavage is 80 per cent. in this series, against 52 per cent. when local measures only were employed. (Dudgeon and Sargent.)

In another series of 25 cases, 19 were treated by thorough washing, the upper part of the peritoneal cavity being dealt with as thoroughly as the lower; of these 18 died. The remaining 6 cases which were, indeed, the most severe ones, being too ill for lavage or evisceration, the appendical region alone was treated by dry sponging. All six of these cases recovered. (Dudgeon and Sargent.)

Although it will weaken my argument somewhat, I must utter a warning against attaching too much consequence to statistics obtained from a small series of cases, for I observe that in 1900, George

R. Fowler reported 9 successive successful cures of general peritonitis by flushing, drainage, and Fowler posture; however, in 100 cases of septic peritonitis following appendicitis, reported in 1904 by this surgeon and R. S. Fowler, the mortality was 67 per cent.

Up to the end of 1905 it was almost the universal practice of surgeons to irrigate in diffuse peritonitis, and all were not so particular about the selection of their cases; indeed, one prominent surgeon of Louisville, Ky., says, "Even in pelvic abscess I irrigate under the liver and loin." I am pleased to say this is not the common practice. Such good men as McCosh, Lund, Blake, Wyeth, Eisendraft, and MacArthur still used irrigation.

Of 1069 cases of diffuse peritonitis collected from the clinics of the best surgeons in America and abroad between the years 1888 and 1904, the mortality was 65 per cent. From 1900 to the end of 1904, of 400 cases the mortality was 55 per cent. In perforation peritonitis, Mayo admits a mortality of about 50 per cent.

Knowing these results, and my own record not being better, I must express amazement at those men who claim that the mortality of peritonitis should not be much over 5 per cent. The whole trouble lies in our conception of what constitutes a diffuse peritonitis; however, in answer to my pessimism I quote with pleasure from a letter received December 11, 1906, from Dr. J. B. Murphy: "I have had, up to date, 38 consecutive cases of general suppurative peritonitis, which includes all the cases I have had since February, 1903, and of these we have had 37 recoveries." With this astoundingly successful record of Dr. Murphy's we have not the right to question any man's report.

It was Murphy's protest against irrigation that attracted the attention of surgeons within the last year. We now note he has many followers. With the exception of Simon J. Young, I find no one offering an explanation for the change of technique. It may be stated as a positive observation that those who do not irrigate have a lower mortality rate than those pursuing the old practice.

Since I disapprove of irrigation for the reason that it disseminates infection and removes the phagocytic cells, by what method then is the purulent matter to be removed? Much of the fluid will be absorbed by the gauze packing placed about the field of initial infection. Such fluid as comes within easy reach should be taken up with gauze pads, gently pressing the pads into the puddles of pus. The forcible thrusting of gauze sponges between intestinal coils into peritoneal recesses is especially condemned.

Some years ago Finney advocated wiping away the dirty fibrinous deposits with gauze. Consider for a moment that peritonitis is an inflammation of the cellular structure below the endothelium, and when this layer of shingles, as some one has aptly called the endothelium, is removed with the clinging fibrin, the blood-vessels and lymph channels are opened for direct absorption. If this is true, surely Finney's practice is faulty technique; and if I mistake not, he admits it.

Placques of fibrin on the intestines should be left undisturbed. Nature is capable of making her own toilet of the peritoneum with infinitely more gentleness, thoroughness, and safety than the surgeon. The reason for this, I think, I have clearly set forth.

Notwithstanding the attitude of the question now, there are conditions under which I would irrigate. When quantities of foreign matter are disseminated throughout the peritoneal cavity, I know of no way to so gently and effectually remove it as by irrigation, especially if we employ a Chamberlin or Blake's irrigator, introduced through the incision in the epigastric region and irrigate from above.

Evisceration produces greater shock and is followed by post-operative tympany. When the intestines are extruded from the abdomen the mere handling of them increases the congestion; and if they are not already tensely full of gas, they quickly become so, so we encounter many difficulties in replacing the intestines. When evisceration is necessary, it is one of the conditions in which I think enterostomy and emptying of the intestines through a Paul tube is quite the proper thing. As a rule, enterostomy is not a desirable procedure except in post-operative peritonitis where paralytic ileus is a conspicuous feature and intestinal toxemia as much as peritoneal sepsis is contributing to the patient's intoxication.

In considering the subject of drainage, there are one or two points that bacteriology has worked out. In peritonitides, due to the colon bacillus, streptococcus, or any of the more virulent germs, infection of the parietal wound is almost sure to occur; but much less likely to do so if the wound is drained down from, but not below, the peritoneum.

Of course we can only determine the nature of the infection by the severity of the symptoms; therefore in the milder cases of diffuse peritonitis I would not drain at all. The drainage of the general peritoneal cavity is physiologically impossible; therefore, "when all peritoneal surfaces look alike, it is a very good rule not to attempt drainage."

The discharge from the drain is largely due to the irritation of its presence. We have three purposes in introducing drainage: first, it is supposed to control hemorrhage; second, we use large gauze drains after the method of Mikulicz for the purpose of segregating a septic field; and, third, with the idea of forming a path of least resistance out of the body. The latter is by far the most frequently attained result, whether desired or not.

When drainage is employed the tube or cigarette is brought out through a stab and in this way we avoid infection of the operative wound. Drainage has some harmful effects upon the prognosis; naturally you would say only severe cases are drained; but this is not the explanation.

In twenty-nine cases of diffuse peritonitis from appendicitis, drainage was employed in seventeen cases; that is, drainage down to the peritoneum only. Of these only one patient died, whereas in twelve instances where there was deep drainage there were five deaths. Another series of twenty-six cases that were deeply drained, fourteen deaths; twenty-five superficially drained, five deaths. These facts were taken from Blake of Roosevelt Hospital and they are significant.

The objections to employing drainage is that it does not drain: that in a short time we have a sinus leading into the peritoneal cavity. Of course drainage increases the tendency to intestinal obstruction and to hernia. If it is possible for a diffuse peritoneal suppuration to subside under the Ochsner treatment, then that forever and a day puts an end to any further debate concerning any propriety of drainage. Murphy employs deep drainage.

The assumption that free peritoneal fluid always gravitates to the pelvis has more than once led us

astray. It was formerly thought that genital tuberculosis was due to the escape of the tubercular bacilli through the visceral peritoneum settling by gravity in the pelvis, there infecting the uterine appendages. Murphy's experiments seemed to confirm this, hence he holds to it as a part of his technique in the management of peritonitis. This idea induced Flower to place patients in the sitting posture. Before him, however, Lennander had sought to secure gravitation to the lumbar region. The line of infection is by no means always in the direction of gravity; furthermore, we can say, upon the authority of Sir Frederic Treves, that the tendency of fluid is not to gravitate toward the pelvis. I was recently impressed with this fact when operating upon a case of gastric perforation some sixteen hours after the accident. After washing out the abdomen, as I imagined, thoroughly, the irrigating fluid escaping through a large tube placed just above the pubis, I believed the cavity comparatively clean, when, as a last touch in the toilet, I raised the stomach up. From under it and the region of the spleen there gushed forth a quantity of food and inflammatory exudate. This fluid had remained in the upper compartment at least sixteen hours; of course had the patient not been operated upon the agglutination of the intestines would have served to still further imprison it until the adhesion melted down under the influence of advancing infection.

It is my observation that Fowler's position does not specially facilitate drainage. The theory that free peritoneal fluid gravitates is held by men of great authority. Kuster, confident in the belief of gravity, turns his patients upon their belly, while Fowler sets them on their butt—"so there you are" (Mr. Dooley).

It is amusing to see how unthinking men have advocated the Fowler position. We are even led to believe that recoveries are due to it alone; and while I think, as above stated, that it has very little effect upon drainage, it is nevertheless the most natural, most comfortable, and most desirable posture after abdominal section. In it the patient is able to relax himself; the viscera fall away from the diaphragm, and deep respiratory excursions are permitted. The patient can move his arms freely, a thing very essential for the comfort of one that has been laparotomized; indeed, I think it cruel to put a patient to bed with the hands confined under the cover. All patients that are subjected to abdominal section should wear a short outing jacket with large loose sleeves, so that they may, without exposure, place their hands above their heads, the favorite posture.

When the focus of infection is removed, the intraperitoneal tension taken away by the escape of the exudate, and drain, if used, put in place, the operative wound is closed; the patient, if very ill, should receive a hypodermoclysis of physiological saline solution from 500 to 1000 c.c., properly dressed, and returned to bed and placed in sitting posture well supported.

Now is the time for the proper observance of those principles laid down by Ochsner. Murphy prefers continuous rectal instillation of warm saline solution to intermittent enemata. Many surgeons give their patients water freely by the mouth. I find it best to withhold all water for twenty-four hours.

If the patient is extremely restless the first twelve hours, I do not hesitate to administer morphine, grain 1-8 or 1-16, to be repeated in two hours if necessary. Should vomiting be distressing, I permit the patient to drink freely of hot soda water. When this is ejected the stomach is quiet. If, however, vomiting persists or should recur with annoying frequency at any time during convalescence, I wash the stomach out. Another indication for gastric lavage is distention of the stomach, as shown by epigastric fullness, frequent belching, or hiccough.

Morphine is not repeated unless the patient is in such condition that there is no objection to its administration.

All drains are removed in forty-eight hours. There is no great hurry about purgatives or stimulating enemata. When the Murphy method is employed, patients pass flatus freely, usually within the first eighteen hours. Yet it is my custom about this time to administer two grains of calomel. The saline enemata invite an easy bowel action. More drastic methods are not required and are of questionable utility.

If a stimulating enema is used, it should be administered with the patient on the left side and the clysis given high into the colon.

Should the patient show reaction from sepsis, but develop great tympany, with vomiting and fast pulse with absolutely no bowel action, that condition we call paralytic ileus. Then an enterostomy with the aid of Paul's tubes should be done. This can be accomplished with cocaine anesthesia.

When the bacteriologists can produce a serum antitoxic to the colon bacillus, then much may be hoped for in the management of certain desperate inoperable cases of diffuse peritonitis. Perhaps it is not visionary to predict that the magician of the laboratory may entirely displace the surgeon.

Now, gentlemen, I have told my tale. The paper is incomplete in many details and original in none. The giants of our profession have been at work in this field; a dwarf upon their shoulders may see farther than they. If one's name is not mentioned, I question if he has the right to cry "stop, thief" for he before me was a pilferer.

The grouping, method, and wandering way are my own; these no man will lay claim to, therefore none have I offended. I respect every man's opinion and concede his right in this unsettled state of the case to follow his own method. I will not decry them if they have a rational basis; but for God's sake let him think for himself and be no man's flunkey.

KOCH'S EMULSION OF BACILLI IN THE DIAGNOSIS OF INCIPIENT THORACIC TUBERCULOSIS.

By WILLIAM MEYER, M.D.,

WEST HOBOKEN, N. J.

My endeavor in this article is the demonstration of the possibility of a diagnosis of early tuberculosis by means of Koch's new tuberculin (emulsion) before we can arrive at a positive diagnosis by any other means. I therefore choose 28 cases of incipient tuberculosis in private practice. These cases were collected during the years of 1905 and 1906.

Case I.—Mr. S., 30 years of age, 6 feet high, weighing 186 pounds when he called first. He had been ailing for about one year. He complained of a sense of constriction in the throat which forced him to make efforts at coughing and clearing his throat, while actually there was no expectoration of any amount present. He consulted two throat specialists, one of whom treated him for catarrh

and cauterized his throat by the electric cautery for about six months, once a week. The trouble did not improve and the patient went to another specialist, who treated him for chronic pharyngitis for four months; but also in vain. The patient called to see me in December, 1905. History: Father and mother living; neither has ever been seriously ill; grandfather and grandmother died both at an advanced age, above 70. He never had any disease, except measles, when a child. He is married and has one child, a boy, who is healthy. His wife was treated for tuberculosis four years ago, but is now well. I examined her and found no evidence of disease. He indulges in drink frequently. His present ailment began in January, 1905, after, what he called, a spree. He never had pains in the chest; no night sweats; no loss of weight. The only symptom was the constriction in the throat, just behind the upper sternal edge. I made the patient undress to the skin. Inspection revealed nothing of note; was well nourished, and good developed chest; expansion was perfect over both apices. Palpation revealed nothing of note. The percussion resonance was slightly impaired above the left clavicle anteriorly and a little less posteriorly. A few crackling râles at the end of a full expiration were audible, while normal expiration did not unveil this fact.

The voice was slightly hoarse. Heart normal. The glands of the body showed no enlargement. Temperature was normal, it having been taken three times per day for several days before and after exercise. Pulse 78. Urine normal. Blood normal. Sputum could not be obtained. I took a cotton wrapped probe, passed same down the throat, and swept all parts that could be reached a number of times; examined the secretion, but could find no bacilli. Throat treatment was of no benefit to him in the past and the patient did not wish any more of it. The patient consented after a few days to the injection of tuberculin (emulsion).

I made the first injection on January 9, 1906, at 8 P.M., the amount injected being 0.0025 mgr. in a solution of sodium chloride and carbolic acid. The temperature was taken at 8 A.M. on the following day and again at noon and at 4 P.M. No reaction. Three days later I made the second injection, consisting of 0.008 mgr. The next morning at 6 o'clock the patient sent for me, complaining of pains in the shoulders and an increased cough; the temperature showed 101° F. at that time. The temperature took a typhoid course for three days, varying from 99.5° F. A.M. to 102° F. P.M. On the fourth day all symptoms were gone. The patient was sent to North Carolina, where he was examined and sent home as nontuberculous. He began to work again and continued so until March, when he caught a severe cold. The sputum now could be obtained and was examined. Bacilli were found by the Board of Health and myself. The patient was sent to Saranac Lake, where he stayed four months and returned home, his throat being well.

CASE II.—Miss C., silk worker, twenty-two years of age. Family history negative. Contracted a lobar pneumonia in September, 1905, from which she never fully recovered. She was examined by two physicians, who pronounced the case pleurisy. I saw the patient first in January, 1906. Examination revealed a crackling sound above the right clavicle. Beyond this there was nothing to indicate any trouble. She coughed and had always some sputum in the morning, which was examined eight times; but the result was always negative. Tuberculin (0.0025 mgr.) at 8 P.M. Reaction occurred at 2 P.M. the next day, which disappeared in twenty-four hours. The patient went to Liberty first, then to Denver, Colo., where she is working at present.

CASE III.—Mr. G. R., upholsterer, aged thirty-six, born in New York. Both parents alive. Mother had a cough for past fourteen years; father healthy. Drinks liquor to excess. Was never sick until August, 1905, when a tight feeling of the chest troubled him. He took cough medicines; found some relief, and went about his work as usual. In February, 1906, he consulted me regarding a hacking cough. Examination revealed a slight depression above the left clavicle. No pain on that side, but he had pain on the right side in the clavicular region. Sputum was scant; present only in the morning. Same was examined four times; no bacilli present. Koch's emulsion was injected and the reaction took place thirty-two hours later. Severe pains all over the body and temperature of 102°, which remained for one day and a half. Sputum was again examined by the Board of Health on February 8, four days after the injection, when bacilli were found to be present. Patient was lost sight of.

CASE IV.—G. B., grocer's clerk, age eighteen. Father died suddenly. Mother died of pneumonia. Patient was always well, until three months ago. Since that time he has had a tickling in the throat; a morning cough with very little expectorate now and then; no blood. Had never night sweats. No diarrhea. I saw him on March 15, 1906. He had lost fifteen pounds during the past year. His chest was well formed, large, and symmetrical. Over the right apex posteriorly the percussion note was slightly less resonant and higher in pitch than on the left side. The breath sounds were rough over the same area, but not continually so; there was no tubular breathing present. On each inspiration a light click was audible over the apex of the left side anteriorly, the resonance was not impaired, râles were absent.

The temperature was normal, pulse 80, respirations 18. The cardiac second sound was a little accentuated everywhere, otherwise the heart was normal. There was a tender spot on pressure over the pylorus, some rigidity, and a slight amount of pain constantly. His breath was garlick-like, a symptom upon which I place some importance in cases of tuberculosis. The rest of the examination revealed nothing. The hemoglobin was 56 per cent.; urine normal. I examined him five times in two weeks but found no change, excepting on two occasions a few fine crepitant râles over the left apex anteriorly. The sputum contained no bacilli, typical or atypical, in seven examinations. Diplococci and streptococci were found the first time. I used new tuberculin, initial dose 0.0025 mgr. Three days later 0.005 mgr., and four days later 0.012 mgr. Eighteen hours later the reaction set in, lasting twenty-four to thirty-six hours. Patient went to France, exact place not known.

CASE V.—A. A., an Italian, aged thirty-five years, father had heart disease and the patient suffered from mitral insufficiency, with good compensation. He developed a cough three months ago, had a frothy expectoration, no bacilli. No physical symptoms, but complained of pain, stabbing in character, underneath the right clavicle. Tuberculin was injected four times, but no reaction took place. This was on March 26, 1906. Treatment: Ichtalbin, heroine, and guaiacol carbonate. Patient gained eight pounds in five weeks and felt better. He re-

turned to me in July, with the same complaints, had also lost six pounds. Examinations, three in number, revealed nothing. Tuberculin was used again, dose 0.008 mgr., reaction taking place twenty-four hours later. On July 29 the sputum was examined again, and a few atypical bacilli were found. The tuberculin was continued in addition to the previous treatment, open air and rest with light exercise were instituted. The dose of tuberculin is 0.008 mgr., every three weeks, reaction very slight and at times none. The patient, being poor, is now working in a silk-mill, has gained fourteen pounds, and keeps up the treatment as far as possible, *i.e.* open windows at night, liberal diet, and hygienic rules. He still takes the tuberculin; he claims it benefits him greatly.

Cases VI., VIII., XI., XXI., and XXII. are somewhat similar and need no individual description. Ages: thirty-two, eighteen, twenty-four, twenty-one, twenty-nine, all working people. Cases VIII. and XXI. were in women. Two had several attacks of tonsillitis; one had occasional night-sweats; in three the hands were constantly cold and bluish. Physical symptoms slight or absent. Sputum, blood, and urine negative. No heart lesions. Family history negative as to lung trouble. All complained of a dry cough. The chest developments were fair. No. VIII. had slight depressions under both clavicles and a systolic murmur over aortic and pulmonary areas (cartilages). Tuberculin was used in all of them. All reacted with one or three injections. One has died since with acute nephritis. Two are attending to their work at present. One has disappeared, whereabouts not known.

Case VII.—F. S., age twenty-eight, electrician. Family history negative. Saw me first in December, 1905. Sputum negative, blood normal, heart normal. Examination revealed a small depression above right clavicle, no other signs. Tuberculin was used and reaction set in fifteen hours later. Patient went to Dr. Hessner, Davos Platz, who confirmed my diagnosis by tuberculin test.

Case IX.—Swiss, aged twenty-eight years, embroiderer. He called on me the first time in June, 1906, had a temperature of 102° and a few râles below the right clavicle anteriorly and posteriorly. Sputum was negative, urine normal, tonsils highly inflamed and enlarged. Tonsils were later on removed. Patient had always been well until December last, when he caught a cold and had suffered ever since from pains in his chest. Lost five pounds; coughs only in the morning. Chest is well developed. Breathing is at times wavy. Tuberculin was used four times with slight reactions the first and last time. He went to Dr. Jacobi (sanatorium), Arosa, Switzerland.

Case X.—Mrs. A. L., age thirty-one, married, three children. No family history. Complained of pain in the epigastrium and indigestion, for which she consulted me. Had had occasional night-sweats. No temperature, no loss of weight. Hands clammy and cold. Voice was whispering. Pectoriloquy was present on one side. The percussion note was slightly impaired over right apex. The rest of the examination was negative. A little sputum was obtained but contained no bacilli, though it did contain a little elastic tissue. Tuberculin was injected and a reaction took place two days later. She was advised to go to Saranac Lake, from where I received a letter from her, but my answer failed to reach her, and I lost sight of the case.

Case XII.—Miss L., aged twenty-eight years, a nurse. One brother died of phthisis, one sister is now in California to be cured of lung trouble. She feels tired and sleepy all the time, poor appetite, has lost some in weight. Has now a sore throat, coughs occasionally, never had night-sweats, no symptoms indicating tuberculosis.

She is anemic. Percussion normal, urine normal. On one occasion I thought I heard a fine crackling sound in the right apex, but failed to find it later. There is a friction sound in the right axilla high up. Dr. Russel of New York examined this case, but he did not state the diagnosis; he put the patient on his emulsions, but the patient vomited the same every time. New tuberculin was injected and a reaction took place within twenty-four hours. She is now taking the outdoor treatment in North Carolina.

Cases XIII., XV., XVI., and XXX. show similar traits and will be described collectively. All the patients are silk workers, ages ranging from nineteen to thirty-four, two men and two women. All had lung troubles in their families, pneumonia, lung abscess, and one tuberculosis. All complained, when I saw them first, of fatigue, soreness in the chest, and an occasional cough. Physical symptoms were: Anemia, poorly nourished, slight depressions above clavicles, chest asymmetrical. Percussion note showed slight differences over the apices more or less in all. Breathing jerky and the expiratory sounds prolonged. Sputum negative, no night-sweats. Three of these reacted to tuberculin. One was killed the day after the injection by an accident; two of these cases are now under the care of Dr. Janssen, Arosa, who verified my diagnosis; one of the four was lost sight of.

Case XIV.—Miss B. v. S., eighteen years old. Family history: Parents both living. She had never been ill until July last, when a diarrhea left her ever since in a debilitated condition with an occasional cough. I saw her in October, when I made an examination which brought out nothing to indicate tuberculosis. Blood was deficient in hemoglobin. I injected tuberculin four times but gained no reaction. Still her cough continues up to date, November, 1906, and the case is suspicious.

Cases XVII., XIX., and XXVIII. have the general traits in common, chest poorly developed, shallow breathers, pain and tenderness in the epigastrium, second pulmonary sound accentuated. Cough lasting from three months to six weeks, very little sputum, containing no bacilli, urine normal. Two of these patients were treated for neurasthenia. All reacted on first injection of tuberculin. One of these patients is now in San Remo, one in Charlotteville, and one at Liberty.

Cases XXIII. and XXV. also show similarities; both had a cough for a few months which did not yield to ordinary treatment. I saw them first in September, 1906. Family history negative. One has mitral stenosis. Both well developed, one had interference of percussion note on right side above clavicle, the other some crackling sounds over the left apex above the clavicle. Sputum was abundant and was examined six times for each; in one case atypical bacilli were found at first examination, but none since. Both reacted severely to the tuberculin. One is now in Davos Platz, the other in some German sanatorium and is being treated by tuberculin.

Case XVIII.—Mrs. St., twenty-eight years old, German by birth, eight years in America; has five children; no uterine lesion, heart normal. Disease began four years ago; dry cough, which was diagnosed by a physician as pharyngitis; another one treated her for kidney trouble, and a third one for indigestion, cancer, etc. I saw the patient first in December, 1905. Examined her and found no lung

symptoms, but a slight cough all the time, hacking in character, very little sputum which showed no bacilli, but a few streptococci. Urine negative, blood negative, slightly anemic, no elevation of temperature; did her daily housework, weight 90 pounds, had lost considerable weight since she began treatment first. Appetite fair, sleep restless, dreams at night; she is melancholic at times, tired most of the time, looks pale, has no tremors, no particular pain, is nervous; her sclerotics are a whitish blue, breath garlicky, nails decidedly curved. No edema, pulse 90 after light exercise. I advised sanatorium treatment, but the patient refused. Then I treated her as best I could at home. Open windows, good hygiene, liberal diet, sitting out of doors about eight hours per day, etc. In January, 1906, her condition was about the same. Another thorough examination proved negative. Sputum again examined by the Board of Health, but also negative; the sputum was examined in all nine times, but always negative. Her bowels were constipated and she complained of neuralgic pains below the scapulas and under the right clavicle. Breathing was of a wavy character over right apex, no râles, there was a murmur in the right axillary region (friction like, pleuritic?). In March a nurse was engaged to enable her to attend better to her condition, as patient was neglectful. On March 6, 1906, I injected Koch's emulsion 0.0025 mgr., no reaction. On March 8 I injected her the second time, 0.005 mgr., no reaction. On March 13 the third time, 0.01 mgr., no reaction. On March 16 and 18 again, with no reaction. Lastly, on March 24, 0.005 mgr.; reaction was severe after thirteen hours, pains in all joints, locally small erythema. Fever at 10 A.M. On March 25, 104° F. (all injections were made at 8 P.M.); this fever increased to 106° F. at 2 P.M. the same day. It showed a typhoid type, *i.e.* a morning remission and evening exacerbation. On March 30 she was free from fever. On March 31 she complained of severe pain in the abdomen, increased cough, abdomen distended decidedly tympanitic. At night she became unconscious, bowels constipated, urine deep colored, sputum examined and bacilli were found. She was sent to Christ Hospital, Jersey City. Dr. Dickinson examined her, but found no lung symptoms, except as found by me; he advised operation for abdominal relief and found a great amount of ill-smelling fluid which was tuberculous. The patient died a few weeks later of tuberculous peritonitis.

Cases XXIV. and XXVII.—Husband and wife Saw me first on September 21, 1906; both had severe colds, as they termed it, for about three months. Both were examined. Husband had fine râles over right apex, above the clavicle, and insufficient extension of chest in that region; the rest of the examination was negative. Wife had mucous râles in the bronchioles of the right apex and right base deep down; pain in the left apex and shoulder and a little blood-streaked sputum; no fever, the temperature having been taken daily for one week, twice a day, before and after exercise. Sputum negative; six examinations each. The husband reacted on the injection of tuberculin; his wife did not; the latter received five injections at intervals of one week, the husband received two injections. Both are Germans, and I made them aware of the seriousness of the disease. They decided to go to the old country. I recommended them to Dr. Fraenkel, and I expect to hear from him in the near future.

Case XXVI.—This patient, male, twenty-two years old, claimed he had tuberculosis at one time, a physician in Brooklyn having made the diagnosis; he prescribed a cough medicine, and patient got well. His sputum was not examined at that time. The former physician had made an examination without removing the patient's clothing. I found no symptoms whatever, except a harsh voice (hoarse). Sputum showed no bacilli in eight examinations. Three injections of tuberculin brought on a mild reaction; the patient is treated at home and receives regular injections at definite intervals.

A request of Dr. Camac, New York, induces me to publish these cases; at the same time I thank Dr. Brown, of Saranac Lake, most sincerely for looking over my papers and for his suggestions.

In order to present a short view of the results obtained I have attached two tables at the end of the article which are self-explanatory. Table I contains in the first column the number of case, next the sex, then the age, amount of bacillary emulsion used, number of injections made, and lastly, the reaction.

Table No. II contains the number of case, character of reaction, sputum before and after injection. Wherever two numbers appear under "after" it means that the first number was sputum which contained bacilli, while the second set indicates that no bacilli were found, *i.e.* after some treatment. Then follows the column of the history of the case, and lastly, the occupation of the patient.

TABLE I.

No. of Case	Sex	Age	Amount of Bac. Emul. Used	No. of Injections	Reaction
1	male	30	a—0.0025 mgr. b—0.008 "	2	10 hours later.
2	female	22	a—0.0025 "	1	18 hours later.
3	male	30	a—0.0025 "	1	32 hours later.

27	1-2 day.	malaise: temp. 101° ..	" 6	. .	. .	neg...	farmwork
28	6 hrs...	headache and vague pains; temp. 100° ..	" 4	" 2	" 1	?	?

*NOTE.—Numbers indicate how many times sputum was examined with results; if two sets of numbers follow under "*After*," it means that the first is positive, and second negative, due to treatment.

Conclusion.—This table demonstrates to me the value of the bacillary emulsion for diagnostic purposes, and it shows further that we have a valuable means of determining an early tuberculosis which we could not positively discover without that means.

446 CLINTON AVENUE

Lupulin.—T. F. Reilly finds lupulin a valuable mild anodyne and hypnotic and often an excellent substitute for more active drugs of this class. He believes it is a safe substitute for the coaltar preparations. For children it is often a good substitute for opium, as also for old people suffering from advanced renal disease, and it is of especial value for sleeplessness and nervousness following a mild debauch.—*Journal of the American Medical Association.*

OBSERVATIONS ON AN IDEAL LOCAL ANESTHESIA FOR SUBMUCOUS RESECTION.

BY F. E. MILLER, M.D.

NEW YORK

APPRECIATING the value of an ideal method of local anesthesia, and believing that there are others who have had unfortunate experiences, I present a method that has been found ideal in my practice and more satisfactory than the solution recommended by me in the *International Journal of Surgery* of February, 1903. I described then a solution, suggested by Prof. William Kelly Simpson of the College of Physicians and Surgeons of this city, of cocaine, 4 per cent., and adrenalin, 1 to 1000, equal parts, used as a spray, and where this could not be applied, I used it in a hypodermic injection between the tonsil and its pillars.

A most satisfactory and ideal anesthesia has been secured since February, 1905, by my associate, Dr. Arthur P. Coll, and myself. We have been able to apply the above-mentioned adrenalin and cocaine so successfully that any submucous resection of the septum can be commenced within three minutes and carried on as long as may be required without pain or hemorrhage and without other help.

The mixture consists of about 20 to 25 grs. cocaine crystals placed in a shallow dish and dropping sufficient adrenalin chloride solution, 1 to 1000, to dissolve the crystals.

The method of applying this solution is as follows: By wetting cotton on the applicator so that there will be no excess of solution, thereby avoiding paralyzing the constrictors of the pharynx, swab over the entire field of operation with applicator. With this solution we have been able to operate for three-quarters of an hour without the slightest discomfort to the patient.

In the last forty cases of submucous resection of the septum, this mixture was used with greatest comfort to my patients, being absolutely free from pain and with minimum of hemorrhage; reducing the former cocaine toxic symptoms, the bane of the nasal surgeon's operations, without general anesthesia.

Formerly, I used a solution of 2 per cent. resorcin and 4 per cent. cocaine as a spray so that the nostrils could be, as it were, prepared for internal treatment without hurting or irritating them by instrumentation. The resorcin also had the effect of not only enhancing the anesthetic power of the cocaine, but changed its excessively bitter and nauseous taste, thus relieving to a large degree its psychic effect.

To further remove this last-named phase and to better the patient's self-control, I administered (and do now administer) immediately before the cocaine-resorcin solution a nerve sedative and vasomotor controller, of

℞ Sodii bromidi,
Potassii bromidi,
Ammonii bromidi, āa.....gr. x
Spts. ammon. aromat.....℥i
Aquæ q.s. ad.....℥iii
Sig: At one dose.

By this means only two patients had slight or partial collapse and were carried to the end of the operation by means of bending the head as far down and forward as possible, and then massaging vigorously the nape of the neck.

Formerly, to make the anesthesia complete, three or four strips of sterilized gauze were introduced,

of size and shape to fit the cavity of the nostril when spread out upon its mucous membrane. These strips were moistened with 4 per cent. solution of cacoine to saturation, and inserted (not too deep down the pharynx) with forceps having parallel blades with handles at right angles, and then smoothed over the entire circumference with force and pressure if necessary. In ten to fifteen minutes these pieces of gauze could be removed and a very excellent anesthesia would have been obtained. This is entirely done away with by the aforesaid procedure.

Sometimes it is very necessary to prolong these operations which usually take, all told, about thirty minutes to an hour, or even longer. This can be perfectly accomplished even without hemorrhage by dipping a probe, wound securely about with small pieces of cotton, into cocaine crystals as mentioned above, and applying it to the membrane when secretion is beginning to return or oozing is occurring. By this means I have taken out without damage, the entire bony and cartilaginous septum of a football coach who had been kicked on the nose, causing a hideous deformity with comminution of the septum, within one-quarter of an inch of its entire periphery, and have lost but very little of the mucous membrane, and have restored the nose, internally and externally, to a perfect cosmetic condition.

THE TREATMENT OF LA GRIPPE.

By P. J. McCourt, M.D.,

New York.

In the Medical Record of December 22, 1906, was an excellent and conservative article on the above subject by Dr. Charles E. Nammack, which should command more consideration than such articles generally receive. I have delayed this paper in the hope that others would offer more encouragement, or suggest a better method in the treatment of that persistent affliction, but none has been presented—at least not in the journal in which we expect to find most help.

Dr. Nammack's opening sentence, if it were definitive, would be a sad confession of our weakness, and one that should make us blush: "There is neither a prophylactic nor a specific for influenza." In this one particular I am happy to take issue with the gentleman; we possess both.

Epidemic influenza invaded the country in a pestilential wave from the overflowed banks of the filthy Neva and other open sewers in Russia, and lesser pest spots of our own perpetuate the cause and its malign results. Under existing conditions the miasm will abide with us as a constant foe, and it is our duty to devise means that will subdue or conquer it. And that duty we shall perform, as we have so many others of equal beneficence. Thus far its medical treatment has not received adequate or intelligent study, and in this respect it is not isolated. We have culpably neglected our materia medica for the knife and the microscope, although the latter has enabled us to cure practically nothing.

Arsenic—not in combination, as in Fowler's solution, etc., but simple, pure arsenic—in alcoholic solution, 1.8000, five minim doses morning and evening, has afforded immunity to a large number of my patients who had previously suffered from repeated attacks of influenza. Not a few of those patients soon became more sensitive to the action of the prophylactic than they had been to the disease, and had to suspend dosage at frequent intervals. The known failures were under 6 per cent.

Gelsemium, tincture of the fresh root, three to five minims in six ounces of water, drachm doses every one to three hours, is practically a specific for almost every step, stage, and variety of la grippe, when free from serious early complications. In the control of influenza this form of the drug has rarely failed me during the past twelve years, and recoveries have been rapid and complete, usually free from later complications or sequel. But fluid preparations of the dry root—infusion, tincture, and fluid extract—were found to be entirely valueless. The dose may be much smaller than that just named, but should never exceed this amount', else it may markedly increase the existing prostration; and, further, it must be reduced as the condition of the patient improves. The drug is also admirably indicated for the entire train of mental and nervous phenomena usually common to the disease, and is the only known remedy for high fever without thirst, whatever may be the pathological condition. Since it now appears reasonably certain that all varieties of la grippe originate from a common infective element, we may infer that the same remedy should prove curative in all; and this inference is justified in practice. Hence it would be but a waste of valuable time to treat its erratic symptomatology as made up of separate entities. Approximate specifics of equal efficacy for other diseases are numerous, but they will not be found among the juices of withered plants, alkaloids, or crude, unknown mixtures.

A single minim of a correctly made fresh-plant tincture is endowed with more, and better, medicinal activity than are ten minims of our official dry-plant fluid preparations, whether "standardized" or not. In the treatment of disease I am a firm believer in the competence of rational medicine rationally administered. But to me there is nothing rational in the exhibition of dead or withered plant-juices, or their alkaloids; and the latter never represent the true medicinal properties of the plant, whether the plant be living or dead. I also believe that in the process of drying, medical plants, aside from losing most of their vital properties, undergo chemical and destructive changes which render them unfit for medical use. This belief is strengthened by the recent investigations of Dr. Cloetta, who could find no cumulative action from the fresh leaves of digitalis, and that vicious property he attributes to changes in the dry leaves.

Attentive study and exact comparative tests in single cases and upon the same patient have fully convinced me, as such crucial tests must convince others, that the simple drug in fresh-plant tincture—or two simple drugs given alternately when both are called for—is more effective in therapeutics than any compound prescription can possibly be. Even when the latter seems to relieve—for it never cures any morbid process—its clinical effects afford no data for future guidance in similar conditions. Warburg's tincture may be taken as an extreme type of the compound prescription. On rare occasions it has shown some efficacy; but that efficacy is limited by the fact that, like all medical mixtures, we can never obtain it twice exactly alike. This irregularity is not always the fault of the pharmacist. The error is often due to the carelessness of our manufacturers, who seldom make a drug twice the same, chiefly owing to a neglect of the "law of proportion." Again, the chemical reaction of several constituent drugs upon each other is still the unknown quantity, and their united

action upon the patient is equally uncertain. Under our present crude and unscientific practice patients usually make a slow and imperfect recovery, often from natural causes or even in spite of our medicine, and we are prone to give undue credit to whatever drugs we happen to be using at the time. At best, this is merely assumption, unless it be presumption. If, on the other hand, we prescribe one or two separate drugs for a known pathological condition and a given group of pathognomonic symptoms, and the patient makes a rapid and complete recovery, we at once possess a valuable guide for the successful treatment of all similar cases for all future time. This is medical science, not mere conjecture, and should be our chief object of attainment. And that object will ere long be attained in the manner I have suggested, for there is no other.

Had we devoted as much time and intelligent thought to the perfection, study, and application of our materia medica as we have to analyzing pathological shadows and nursing microbes, there would be fewer therapeutic nihilists and medical machinists among us.

233 West Twenty-third Street.

The Histology of the Skin Lesions in Varicella.—E. E. Tyzzer states that the study of lesions excised from eleven cases of varicella in adult Filipinos shows that the initial change consists in the appearance of peculiar eosin-staining inclusions within the nuclei and cytoplasm of epithelial and various other cells. Direct division of nuclei without subsequent division of the cytoplasm is associated with these inclusions. Cells undergoing these changes often become enormous during their degeneration. After these cell changes the typical varicella process consists of a rapid destruction of small areas of the epidermis associated with exudation and vesicle formation. The development of the vesicle is attended by the formation, about the epithelial cells, of numerous fibers. A certain number of lesions are infected by bacteria, as the result of which they become pustular. In such lesions there is more or less destruction of the papillary layer, which accounts for the scars frequently following an attack of varicella. A conclusion has not been reached concerning the nature of specific inclusions in varicella and no important evidence has been found in favor of the hypothesis that they are parasitic organisms. Inoculations of the cornea of the rabbit and the skin of the monkey with the contents of varicella vesicles have in all cases yielded negative results.—*The Philippine Journal of Science.*

Tics in Children and their Educational Treatment.—Charles Herrman calls attention to the frequency of tics and the discomfort which these conditions cause. Many tics have their origin in childhood. As in all the neuroses of childhood there are two important factors in the etiology of this affection: the inherited predisposition, the favorable soil; the environment including the method of training. Often the movement or gesture was originally performed with a purpose. Tics may affect almost all parts of the body; several may be combined. The mental state of these patients is characteristic. Equilibrium is lacking. The will is not under control. There is difficulty in concentrating the attention, shown in impulsiveness, restlessness, impatience, or irritability. As to treatment, any abnormalities near the site of the muscles affected should receive attention. Except tonics, drugs are, in most cases, useless, unnecessary, or contraindicated. The regulation of the diet and mode of life are of great importance. Violent exercise should not be indulged in. The essential treatment, however, is educational. It consists of two parts: immobilization primarily of the parts affected; active exercises primarily of the parts affected. The patient is seated before a mirror and is told to remain perfectly quiet like a statue for a stated time. An occasional word of encouragement or praise is often of advantage. Active exercises of the muscles are then directed by the physician. These exercises should be gone through with three times a day at stated times. Regularity and punctuality are essential. The writer has treated ten cases according to the method which he describes. In six the movements have entirely ceased.—*Archives of Pediatrics.*

A Note on Syphilis and Cancer and on Some Protozoa.—J. J. Clarke discusses some of the protozoa and the spirochetes. The latter had often been confused, he says, with spiral bacteria. Syphilis is a disease in which the life cycle of the parasite is completed within the human host, so that if *Spirochæta pallida* is related to the causation of the disease other and larger forms must be found in the tissues. The author figures the various stages of some of the spirochetes as developed in the intestine of the common gnat, and claims that some of them were described by himself as early as 1894. Since then he has observed similar bodies in the scrapings from tertiary ulcers. He is an advocate of the theory that cancer is caused by protozoa, and is convinced that the common forms of cancer and sarcoma are caused by more or less local infections by protozoa and differ from the infective granulomata only in the more intimate character of the parasitism and the more complicated life-history of the parasites.—*British Medical Journal.*

Bilharziosis.—Roux declares that the portal vein, the veins of the pelvis and those of the bladder and of the rectum are the ones in which the bilharzia is most frequently found. It is remarkable that the portal vein contains only young parasites whose sexual activity has not yet begun. This infection is rarely seen in those of the upper classes. The blood of these patients has a tendency, according to Goebel, to coagulate rapidly after it is drawn from the blood-vessels. This phenomenon depends upon secretion of the parasite as yet unknown. In regard to treatment prophylaxis is most important. The writer emphasizes the necessity of instructing the inhabitants of Egypt concerning this disease. They should be told of the danger of drinking impure water and of bathing in it. They should also be taught the rôle which the urine and feces of persons suffering from this disease plays in its propagation. Such instruction would be of inestimable value to the inhabitants of this country.—*Le Caducée.*

The "Home Sanatorium" Treatment of Consumption.—Joseph H. Pratt gives an interesting report of the work which he has been doing in relation to tuberculous patients. The "class" of patients is sometimes spoken of as a "home sanatorium." It bears about the same relation to a sanatorium that a correspondence course does to a college course. A nurse who devotes her time to visiting the members of a class is called a "friendly visitor." The writer's patients have all been poor, some of them not very intelligent. Before any individual is admitted to the class he must promise to give up all work, live the outdoor life, and obey all the rules of the class. The clinical history of the patient is taken and a complete physical examination made. Once a month the lungs and sputum are reexamined. The nurse looks for suitable tenements for the members. The prescribed diet consists chiefly of milk, bread, fruit, butter, and oil. Cotton-seed oil is a satisfactory substitute for olive oil. No exercise is allowed for the first few weeks. When the temperature becomes normal for the entire day the exact amount of exercise is prescribed. Of the nine patients who have been members of the class for three months or more all show a gain in weight. In five of the nine cases the disease has been arrested. The writer appends the histories of a number of cases.—*Bulletin of the Johns Hopkins Hospital.*

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

THOMAS L. STEDMAN, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51 FIFTH AVENUE.

New York, February 23, 1907.

THE INCOME OF THE PRACTISING PHYSICIAN.

THE fact has been evident for some time in Great Britain that the earnings of the medical practitioner have been exhibiting a progressive decrease. This diminution of income has not unnaturally aroused certain members of the medical profession, who both in medical and in lay journals have somewhat clamorously advertised this unfortunate state of affairs. Some two months ago one of the leading newspapers of London devoted a considerable amount of space in its correspondence columns to a discussion of the situation, and medical practitioners from all parts of the country entered with apparent zest into the task of bewailing their lot and of considering the reasons for the evil complained of. It was agreed on all hands that hospital abuse was an important factor in the lessening of the doctor's gains, and that there was no prospect of matters becoming better in this respect. All large hospitals in Great Britain are free and many sick persons avail themselves of the benefits of such institutions who can well afford to pay a medical man. Another fruitful cause of diminished income is the multiplication of medical clubs in Great Britain: the competition among physicians is so acute that clubs are now taken at an absurdly low rate, four shillings (one dollar) per capita for men, women, and children per year being an ordinary fee. Prescribing by druggists is another means whereby, it is stated, physicians in England are frequently mulcted of their just dues.

In America hospital and dispensary abuse is as flagrant and as prevalent, perhaps, as in Great Britain, although, owing to the different conditions existing, it is not exhibited in the same way. Club practice has not as yet obtained the hold in America that it has gained in Great Britain, but signs are plentiful that the methods are taking root and becoming more and more popular. Of course prescribing by druggists has always been largely in vogue in this country and a source of very considerable loss to the medical practitioner. By some physicians in England it is proposed to put down this custom by the strong hand of the law, but exactly how this is to be brought about it is difficult to understand.

Competition is more severe among American physicians than among British practitioners, but on the other hand medical fees here are on the whole far higher. While allowing that members of the medical profession are as a rule underpaid, it may be pointed out that two potent reasons for the diminution of income are usually overlooked. These are the decrease in morbidity and the greatly improved methods of treatment of the present day. Hygiene and sanitation have abolished many of the great epidemics of disease which in times past were wont to bring much grist to the doctor's mill, while the introduction of new and more scientific modes of treatment have to a great extent curtailed the duration of the disease and have in a corresponding degree reduced the doctor's income.

CORNEAL GRAFTING.

AMONG the most ingenious applications of the methods of plastic surgery is the substitution of a transparent membrane for portions of the corneal tissue which are impervious to light. The operation was first suggested in the early part of the last century, although the act of replacing a clouded human cornea with that from an animal was not carried out. During the succeeding years numerous efforts were made to overcome the many difficulties which surrounded the operation, but without success, so that the procedure was finally abandoned, only to be revived again during more recent years. It seems that the first successful operation was performed by Sellerbeck in 1878, who replaced the clouded cornea of a man who had become blind as the result of a gonorrheal ophthalmia with that from a small child in which enucleation had been rendered necessary by a glioma of the retina. Healing took place without any reaction and the patient could read print of moderate size in about two weeks, but unfortunately in another week cloudiness appeared at the edges of the graft and soon thereafter vision was again completely lost. Subsequent attempts made by different operators were likewise unsuccessful and the idea of providing an optically perfect cornea by this means was practically abandoned. It was believed, however, that the procedure might prove of service in another direction, namely to replace ulcerated or incompletely cicatrized areas in the cornea with a more substantial tissue basis, an idea far removed from the original purposes of the operation. The application of this principle has been made the subject of a communication by Zirm in the *Wiener klinische Wochenschrift*, No. 3, 1907, who reports a permanently successful operative result in a man who had become almost totally blind as the result of a corneal opacity due to lime burns. The material for the grafts was taken from the eye of a boy, which had been removed on account of extensive trauma. Although one of the flaps failed to adhere, the other became firmly united and the man's vision was sufficiently restored to permit his going back to work at his former occupation.

An inquiry into the reasons for the failures in previous attempts seems to show that aside from imperfections in the technique an insufficient degree of attention to means for maintaining the nutriment of the flap was the cause for a majority of the failures. It is essential that the material for the graft be obtained from the human subject, and the cornea must be well nourished and not the subject of any degenerative processes. Zirm claims that experi-

ence has shown that animal grafts cannot be employed. Deep narcosis, strict asepsis, and the avoidance of all antiseptics are among the most essential details connected with the operation. The flap must not be handled with instruments, but with small pads of moist gauze, and kept warm with steam until ready to be applied. It is fixed in place with two crossed sutures, which are inserted through the conjunctiva. The cases moreover must be carefully selected, and it would appear that the centrally located opacities furnish the best opportunities for successful grafting, particularly if the surrounding areas are still well nourished. Plastic operations on the eye, especially when they aid in the restoration of sight, must be accounted among the most useful among this class of surgical procedures, and although one swallow does not make a summer, the success attained by Zirm in this one case should lead to renewed interest in what has almost been abandoned as a useless operative interference.

ALCOHOL IN THE NUTRITION OF DIABETICS.

Among the questions of paramount interest in the study of diabetes is that relating to the source of acetone, and that this is not merely a theoretical one is shown by the increasing attention which is accorded to the idea that the acetone bodies exert an important bearing on the production of one of the most feared complications of diabetes, namely diabetic coma. The ideal method of treatment includes not only the means whereby the sugar is made to disappear from the urine, but also that whereby the ingestion of albuminoids is reduced and that of the fats increased. In severe cases of diabetes albumin will often induce more active sugar elimination than certain carbohydrates, and it is quite generally believed at the present day to be the most probable source of the acetone bodies. Fat on the contrary does not seem to play any considerable part in the production of these substances, but it constitutes a valuable and harmless source of nutriment, by the aid of which the carbohydrates in the diet may be readily displaced. This assumption has met with some opposition, however, and it is claimed that the fats may also serve as a source for the production of acetone.

Some recent investigations by Benedict and Torok, reported in the *Zeitschrift für klinische Medizin*, Vol. 60, Nos. 3 and 4, seemed to show that in diabetics this is a fact, although control experiments in nondiabetic patients were by no means conclusive. Alcohol was then employed as a substitute for the fat and the result was most favorable. The writers found that alcohol will bring about a marked diminution in the amount of acetone and also reduce the quantity of sugar, while at the same time it supports the nutrition. The administration of alcohol is particularly indicated in the severe cases in which it is the aim to render the patient as free from glycosuria as possible. For with an exclusive meat diet the danger of acetonuria and coma is always present, and it is therefore most desirable to replace some of the fat with alcohol. The amount of alcohol depends on the severity of the individual case; from one-half to one liter of light wine may be administered with impunity daily for prolonged periods. The exciting or depressing properties of alcohol seem to be less marked in diabetics than in others, which reminds one of the tolerance displayed by diabetics to opium. In order to avoid abuse of the alcohol it is well to regard the latter as a medicine and to administer it as such rather than as an article of diet.

There are of course self-evident contraindications against the employment of alcohol in diabetes. Among these are albuminuria, especially when this is increased during the administration, neuritis, arteriosclerosis, as well as diabetes in children, where dietetic precautions are also often without effect.

The Effect of Gastroenterostomy on Gastric Digestion.

Although it is something over twenty-five years since Wolfler popularized the operation of gastroenterostomy, it must be confessed that the beneficent effects of the operation have not been altogether satisfactorily explained. It is usually assumed that the procedure owes its happy results mainly to the improvement in the drainage of the organ and in its motility that is brought about, and although changes in its secretory activities have also been predicated, these do not appear to have been studied with very fruitful result. The problem has been made the subject of extended researches by Katzenstein, who publishes some very interesting conclusions in the *Deutsche medizinische Wochenschrift* of January 17 and 24, 1907. By means of operations on dogs, and digestion experiments, he was able to determine that after both anterior and posterior gastroenterostomy bile and pancreatic juice enter the stomach. During the first period after the operation this flow is very profuse, but later it occurs more or less periodically, and it has, as a consequence, the reduction of the gastric acidity, both through its direct chemical effects and through a reflex inhibition of the production of hydrochloric acid. The digestive activity of the pepsin is also diminished, whereas tryptic digestion is not impaired to any noteworthy extent. The effect of the gastroenterostomy is, therefore, to reduce very largely the value of the stomach as a digestive organ through inhibition of both pepsin and hydrochloric acid formation. The result of this is to bring about the conditions most favorable for the cure of peptic ulcer and the prevention of recurrences of the condition, and the surgeon, in resorting to the operation, is making use of a directly remedial measure. These advantages may be still further enhanced by a suitable diet, which should be deficient in proteid in order not to encourage hydrochloric acid and pepsin formation, and should consist largely of fats and carbohydrates, which favor the secretion of bile and pancreatic juice. The meals also should be small and frequently repeated, and the administration of large quantities of fluids, particularly water, is also advisable. In spite of these very strong arguments in favor of gastroenterostomy in the treatment of ulcer of the stomach, Katzenstein believes that the malady is essentially a medical one, and that patients should be referred to the surgeon only when the internist has exhausted the resources at his command. In dealing with cases of gastric cancer the conditions are somewhat different, and here, particularly if there is obstruction, the improvement achieved is largely the result of the drainage of

the stomach that is brought about. The author suggests, however, that the remarkable instances of improvement, or at least arrest of the disease, that sometimes are observed after gastroenterostomy may be the result of the local application of trypsin to the surface of the new growth that is effected by the entrance of the duodenal secretions into the stomach.

The Effect on the Circulation of Pressure on Painful Points.

The fact that on making pressure over supposably painful points more or less pronounced changes in the pulse rate and in blood pressure are produced in dealing with actual disease conditions, whereas this is not the case if there be no real basis for the complaints of the patient, has been found a useful measure for the detection of malingerers. This phenomenon, which is sometimes known as the Mannkopff or Mannkopff-Rumpf symptom, is made the subject of an explanation by Rumpf in the *Münchener medizinische Wochenschrift,* January 22, 1907. He states that pressure on, or friction of, painful points in certain cases of general neuroses or neuralgias may evoke changes in the domain of the circulatory system which may manifest themselves either as a simple increase in the frequency of the heart, as a preliminary slowing of the pulse of short duration followed by an increase in its rapidity, or as a decrease in the size of the pulse. In some instances cardiac arythmia is observed, and in others cyanosis of the face or abnormal secretion of perspiration is noted. The effect of such stimuli may also be either to raise or to lower the blood pressure. All of these changes subside within a short time after the cessation of the painful stimulus. In order to guard against errors in making this test, certain precautions are necessary, however. The patient must be in a hospital, and must have been lying for some time on the bed or couch on which the examination is to be made. He must also have no idea of the significance of the test, and must have been subjected to several previous examinations in order that the mere unaccustomedness of the manipulations may not give rise to error. The heart's action must be regular and the pulse preferably under one hundred. During the examination the patient must breathe quietly and evenly, and must not hold the breath or make straining efforts. In addition to the supposedly painful areas, corresponding spots on the other side of the body should also be tested, and the effect must be limited to the painful side. It is also desirable to repeat the examination on several different occasions.

Andrew Lang on Influenza.

From being a sceptic, Mr. Andrew Lang, the distinguished English litterateur, has become an ardent convert to the doctrine that there is really such a disease as influenza. He says of himself, in a recent number of the *Illustrated London News*, that he "has been the victim of a malady in the existence of which he was an unbeliever. No man," he said, "however credulous, can believe in everything, and I 'took the Wilkes and Liberty' to suppose and assert that there is no such thing in nature as influenza. My causes of scepticism were the usual causes. I never had suffered from influenza. No house in which I ever found myself was haunted by the alleged malady. I was wrong, and am now in case to appreciate an argument of the Chinese medical profession. These learned men believe in demoniacal possession. When their European confrères say, 'Oh, you mean epilepsy, hysteria, and so on,' the Chinese reply: 'Excuse us, we don't! We know all about hysteria and epilepsy, at least as well as you do; but demoniacal possession is quite another affair, with peculiar and distinctive symptoms.' That is also the case with influenza. It may resemble a common cold, but its distinctive symptoms, as in the parallel affair of diabolical possession, are unmistakable. Indeed, I rather think that diabolical possession and genuine influenza are much the same thing. Influenza at once attacks the human mind, and produces the queerest phenomena. Certainly under the dominion of this fiendish malady I exercised mental faculties of a kind which I do not possess when I am in ordinary health. A critic, the late Mr. Henley, I think, once asked, 'What could not Mr. Lang do if he only had genius?' Nobody was able to reply, but when I had influenza I *had* genius. Unluckily, there was no money in it, and I would rather be devoid of the genius than have it with influenza thrown in; inspiration is all very well, but one may purchase it at too high a price."

Cardiac Suture.

Some ten years have elapsed since the first practical demonstration of suture of a wound of the heart was made, one of the earliest cases reported having been that of Dr. Daniel Williams in the Medical Record of March 27, 1897. Although at first unsuccessful in saving life, further experience with the procedure has shown its feasibility, and a considerable number of reports are at hand to point to its value. Thus, among a series of 128 cases which have been collected by Lenormant (*Gazette des Hôpitaux,* 1906, No. 104), eighty-one patients died and forty-seven were cured, a result which must be favorably regarded when we consider the extreme danger which attends this condition. The majority of the reports deal with cases in which a cutting or penetrating wound of the organ occurred and only a relatively small number are concerned with the suture of gunshot injuries. Another interesting fact is that of all the cases in which the exact localization of the trauma was determined only six instances of injury to the auricle are recorded. The remainder relate to injuries of the ventricle, in which the results of suture of the left ventricle are apparently twice as good as in those of the right. Complicating injuries, such as those of the septum, the coronary arteries, or the valves, are invariably fatal; those of the neighboring thoracic and abdominal organs also render the prognosis particularly grave, although two favorable cases have been published in which there was a simultaneous injury of the heart and the lung. If death occurs during the first few hours after the injury it is due to shock, acute anemia, or intracardial trauma, but when it takes place after the second day it is caused by infection of the pleura, the pericardium, or the lung. It is found advisable not to drain any serous cavity which may be opened during the operation of suture, as the dangers of infection are greatly increased by this procedure. Needless to say the most rigorous aseptic measures are necessary to insure a successful outcome, and if these have been adhered to, both pleura and pericardium may be closed without fear of subsequent trouble. In opening the pleural cavity care should be taken not to make the incision any larger than absolutely necessary, for the pneumothorax which may follow is an element of considerable danger.

The Effect of Cooking by Gas.

An editorial in the *Lancet* of February 2 discusses this question from both the chemical and clinical points of view. It is reassuring to learn that the differences between this method and the more familiar ones as to sources of fuel cannot be looked upon as a serious matter from the point of dietetics. Cooking by gas brings up the question as to what effect if any the products of this combustion are likely to have upon the meat. The chief of these products are carbon monoxide, acetylene, and sulphurous acid. The two former form molecular combinations with the coloring matter of the blood, but at the high temperature of the cooking process it is unlikely that such a combination would take place. Moreover, a full air supply would prevent either from being permanently absorbed. Meat during cooking is emissive rather than absorptive. Any difference in cooking must be referable to the manner in which the heat is applied. Open roasting is undoubtedly superior to close roasting. The article in question expresses the view that the cooking of meat by gas is less satisfactory than cooking by the open roast method, because in the former case the joint is cooked partly by ascending heat currents and partly by steam. According to this view, cooking by gas may be regarded as a hybrid process, that is to say, part boiling or steaming and part roasting. The constant stream of steam over the surface of a joint of meat is calculated to extract some of its flavor and to exert a toughening effect on the tissues of the meat.

The Treatment of Auditory Sclerosis.

In sclerosis of the auditory apparatus it is believed that an increase in the blood pressure is the primary cause of the attendant symptoms—vertigo, tinnitus, and deafness. For this reason it has been suggested by Malherbe in the *Bulletin Médical*, No. 81, 1906, that Trunecek's serum be employed in the treatment of the condition. This serum, which has been more or less extensively used abroad in the treatment of arterial sclerosis, has been modified by Malherbe so as to include nitrate of pilocarpine. His method is as follows: Three cubic centimeters of the serum is injected into the gluteal region and this is repeated at intervals of two or three days until twelve doses have been given. In two weeks the treatment is repeated. A strong and a weak serum are used, the former containing twice as much pilocarpine as the latter. The injections are followed by a well-marked effect on the pressure in the peripheral vessels through the agency of the vasomotor nerves and this effect of the original serum is heightened by the pilocarpine in the modification. The treatment is particularly serviceable, according to the writer, in the early cases of the disease, in which the vessels still possess a certain degree of elasticity, and in these instances the tinnitus and the vertigo are greatly helped and the deafness may also be improved. In the forty cases reported by the writer each patient received from twelve to thirty-six injections; in twenty-one the result was excellent, in sixteen it was good, and in the others it may be called doubtful. But even in the latter class of cases where, on account of a sclerosis in the labyrinth, total deafness was present, some of the patients stated that after treatment they could faintly perceive certain sounds, the perception of which had totally disappeared. These experiences would apparently indicate that the Trunecek serum injections might form a valuable adjunct to the local treatment.

News of the Week.

State Health Report.—In his annual report to the Legislature, State Health Commissioner Eugene H. Porter submits that in order to safeguard the water supplies of the State more efficiently the Commissioner should have the authority to order a town to remove its sewage from the State waters if it seems desirable. He also suggests that a commission might be appointed to aid the Health Department of the city of New York in controlling the pollution of New York harbor. The inspection of packing houses and slaughter houses, as well as the examination of their products, showed serious deviations from the proper standards, and it is proposed to continue this work as actively as the appropriations permit. Twenty-one cities show a lower death rate than in 1906, and seventeen a higher death rate. Rome, Ogdensburg, and Troy have the highest death rate, and Johnstown and Tonawanda the lowest. The average city death rate was 15.9, and birth rate 19.7 per 1,000 population. Nine cities—Albany, Cohoes, Hudson, Middletown, Newburgh, Rensselaer, Troy, Watertown, and Watervliet—reported more deaths than births. Albany and Troy show the smallest birth rate, and Dunkirk and New York the largest. Last year there were 183,012 births, 140,773 deaths, and 87,870 marriages, while 9,401 still births were reported. Last year the second highest monthly mortality occurred in August, and was due to 2,339 deaths of children under two years of age from diarrhea and enteritis. More deaths occurred from this cause in this month than from any other disease in any other month, and the Commissioner makes this a ground for recommending that a more efficient system of milk inspection be instituted. The subjects of car sanitation and of the examination of the eyes of school children are also discussed.

Hudson River Ice.—The Merchants' Association of New York, through Mr. Edward Hatch, Jr., chairman of the association's committee on pollution, has sent to Governor Hughes a letter alleging that much of the ice now being cut in the Hudson river is unfit for domestic consumption, and is dangerous to health. The statement is made that it is estimated that 2,500,000 tons of ice are harvested annually on the Hudson for consumption in or about Greater New York. The population of the drainage area of the Hudson Valley is not far below 700,000, and the sewage from this number of persons is discharged into the Hudson river or the tributaries thereof. In addition the farm and barnyard drainage and surface wastes find their way, eventually, into the river. Chemists sent out by the association to examine samples taken from the ice that is being cut and stored allege that most of the ice, at either the top or the bottom of the cake, showed evidence of contamination with intestinal germs, as the result of both chemical and bacteriological examinations. Especially bad is said to be the ice cut on the fields between Albany and Troy, and for five miles south of Albany. Near Albany and elsewhere on the river ice is cut close to the large sewer outlets. Dr. E. H. Porter, State Superintendent of Public Health, in his annual report to the Legislature, complained that he did not have enough money appropriated for his department to enable him to put a guard on the harvesting of ice, and questioned whether he

had the authority to prohibit the cutting of ice from lakes and rivers where it was supposed that pollution existed.

Department of School Hygiene.—The establishment of a department with this title, and intended for the greater protection of the health of school children, is being considered by members of the Board of Education. The new department would be independent of the work of the now existing Department of Physical Training, and would concern itself with such matters as the print of the school books used, the nature of the desks, benches, and other school furniture, etc.

The Milk Question in New York.—The Board of Aldermen has taken up the milk question, and an ordinance has been proposed providing that all milk sold at retail in this city shall be either sterilized or pasteurized, unless the milk has been bottled in dairies under the supervisioin of inspectors of the Health Department, and each bottle bears the Health Department's seal placed on it by one of the Department's inspectors. Several public hearings are to be held before the ordinance is to be reported to the Board.

The Milk Question in Illinois.—In the course of an investigation carried on by the State pure food authorities in Illinois it was found that only about 30 to 35 per cent. of the milk sold in the various cities visited was in the condition it should, and easily could, have been in if the ordinary sanitary regulations had been observed in collecting and handling it. In the course of several weeks' special work 1,400 samples were analyzed, and, ignoring entirely the question of the unclean product sold and unclean vessels, there were brought seventy-six suits for cream or milk adulterated with formaldehyde, seventeen for skim milk sold as standard milk, five for milk both skimmed and watered and sold as standard, twelve for milk below standard and sold as standard, and thirty for watered milk, of which seven were against farmers delivering milk to creameries or shipping stations. In most cases the defendants pleaded guilty; the others are fighting out the issues in court.

Emergency Health Conference in Chicago.—Criticism of the Chicago City Council and its position relative to questions of public health, particularly its opposition during the last five years to the erection of an isolation hospital for the treatment of contagious diseases, marked several of the speeches at an emergency conference, held in Chicago on Sunday, February 10. Several resolutions were introduced at this meeting, the first of which approved the employment of a large corps of physicians for regular school inspection; a second resolution provided for the appointment of a committee of eight to urge an improved system of milk inspection, while the third resolution asked for the appointment of a committee to take further steps for securing a change in the hospital ordinances. The committees are to be composed of two representatives of each of the organizations represented in the meeting, namely, the State Board of Health, City Health Department, Chicago Medical Society, and Illinois Federation of Women's Clubs.

Salaried Ambulance Surgeons in Chicago.—As the result of the transference of the Chicago police ambulance to the jurisdiction of the Health Department, the Chicago City Council has voted to appoint sixteen ambulance surgeons, at a salary of $100 per month.

Infectious Diseases in Schools and Colleges.—In consequence of an epidemic of grip which has laid up half of its pupils and teachers, the seminary of St. John the Baptist in Brooklyn has been temporarily closed, and the seminarians sent to their homes. In Ithaca, N. Y., nearly a hundred cases of diphtheria and scarlet fever have been reported in the last few weeks, and though most of these have been among the townspeople, many of the Cornell students have left Ithaca to avoid infection. Amherst College has been closed until March 1, owing to the outbreak of scarlet fever among the students. About thirty students are ill with the same disease in Wheaton Seminary at Norton, Mass., which has been closed for an indefinite period. Three cases of scarlet fever have been discovered among the students at Harvard. Eighteen or more scarlet fever cases have occurred in Williams College, and it is thought that the authorities will decide to close the college. In this instance the source of the infection is thought to have been found in the milk supplied by a dealer in whose home an unreported case of the disease was discovered.

The Steamboat Whistling Nuisance.—The Board of Supervising Inspectors in Washington is preparing regulations under which will be inforced the law passed last month prohibiting useless and unnecessary whistling by steam craft. At a recent meeting of the board the possibility of requiring vessels to be equipped with whistles giving forth more melodious sounds than those now in use was discussed, and it was decided that investigations relative to this question and to the carrying power of the sounds emitted, as well as the intensity of the light signals used, should be instituted.

Tuberculosis in the Navy.—According to the statistics reported tuberculosis in the Navy and Marine Corps has increased from a ratio per thousand of 3.2 in 1895 to 6.1 in 1905. As one factor in the effort that is being made to combat the disease an abandoned Army post in Colorado has been turned over to the Navy Department, and is being converted into a tuberculosis sanatorium. This is New Fort Lyon, situated at an altitude of 3,800 feet, on the north bank of the Arkansas River, five miles from the town of West Las Animas. The climatic conditions are said to be excellent, and sufficient buildings are at the disposal of those in charge to provide adequate accommodations for the prospective patients.

No Dentists for the Naval Service.—The appropriation of $50,000 for the purpose of providing thirty dental surgeons for the Navy has not passed the House, in spite of the earnest efforts of those interested in the welfare of the service.

Meningitis in Salt Lake City.—During the past six weeks cerebrospinal meningitis has been epidemic in Salt Lake City, and over thirty deaths have occurred from this cause.

Cerebrospinal Meningitis in Belfast.—Because of the alarming mortality from cerebrospinal meningitis at Belfast, and the generally high death rate, owing to unsanitary conditions in many parts of that city, the Government has adopted the unusual course of appointing a naval commission to inquire into the situation.

International Congress on Infant Hygiene.—The second international congress of "Gouttes de Lait," an organization devoted to the protection of child life, will be held in Brussels Sep-

tember 12 to 16, 1907. The first congress was held in Paris two years ago, and a systematic movement having for its object the prevention of infantile mortality was organized. The work falls under three headings, viz. to give advice to mothers, to encourage breast feeding, and to distribute milk to those infants for whom breast feeding is either impossible or insufficient. The president is Dr. A. Devaux of Brussels, and the general secretary is Dr. Eugène Lust of Brussels. The subscription for members is twenty francs, and for associates ten francs. The treasurer is M. Sterckx, 3 Rue Beyaert, Brussels.

The Suit Against Dr. Doyen.—The Public Prosecutor in the First Tribunal of the Seine has presented his conclusions in the suit brought by Mr. Geo. Crocker of San Francisco to recover from Dr. Doyen $20,000 which the surgeon received in 1904 as the result of a contract for treating Mrs. Crocker for cancer. The opinion uttered was in Dr. Doyen's favor, and it was stated that Mr. Crocker's contention that at least a portion of the fee should be refunded was not well founded, because Dr. Doyen had ceased his visits only at Mr. Crocker's request, and not of his own volition. A decision is to be rendered shortly.

Aid for the Famine Sufferers in China.—Nearly $60,000 has been collected by the Red Cross organization for the aid of the victims of the famine in China. It is reported that smallpox has broken out in the camps of the refugees, and that the relief measures are wholly inadequate.

"The Journal of Inebriety" begins the fourth decade of its useful existence with a new department devoted to the physiological and psychological therapeutics of inebriety and drug addiction. To this end arrangements have been completed by which the *Archives of Physiological Therapy* has been consolidated with, and will hereafter be published as a part of *The Journal of Inebriety*. Henceforth, in addition to the various phases of this subject which the journal has presented, the therapeutic effects of hot air, radiant light baths, electricity, massage, psychotherapeutic measures, and other physiological means will occupy a prominent space.

Dr. Byron Robinson's Jubilee.—The *American Medical Compend* of Toledo devotes its issue for January to a celebration of the twenty-fifth anniversary of Dr. Byron Robinson's entrance into the profession of medicine. This well-known anatomist was graduated from Rush Medical School, Chicago, in 1882, and practised for a while in Grand Rapids, Wisconsin. After studying in Europe for several years, he was called to the chair of anatomy in the Toledo Medical College, which he occupied for two years. In 1891 he removed to Chicago, where he now resides, being professor of gynecology and abdominal surgery in the Illinois Medical College, attending gynecologist to the Woman's Hospital, and consulting surgeon to the Mary Thompson Hospital. Dr. Robinson has earned an enviable reputation as an anatomist, an original investigator, and a writer, and the story of his work is told in the *Compend* by more than a score of his pupils and admirers.

Dr. Le Roy Broun of this city, at a recent meeting of the governors of the Woman's Hospital in the State of New York, was elected surgeon to the hospital.

Dr. M. D. Lederman of this city has been appointed Attending Aurist and Laryngologist to the Lebanon Hospital.

The Ninth Harvey Society Lecture will be delivered by Prof. W. T. Councilman, Professor of Pathology, Harvard University, at the New York Academy of Medicine, on Saturday evening, February 23, at 8:30 P.M. Subject: "The Relation of Certain Leucocytes to Infectious Diseases."

American Anti-Tuberculosis League.—The next meeting of this organization is to be held at Atlantic City, N. J., June 1 to 4, 1907, under the presidency of Dr. George Brown of Atlanta, Ga. The chairman of the Reception and Entertainment Committee is Dr. Edward Guion, Atlantic City, N. J.

Saginaw (Mich.) General Hospital.—In connection with this hospital a nurses' home has been opened, with accommodations for thirty-six persons. The building, together with the furnishings, is the gift of Mr. and Mrs. Charles H. Davis of Saginaw, and is to be known as the Davis Nurses' Home. Miss Annie M. Coleman is superintendent of the hospital.

Brooklyn Home for Consumptives.—By the will of the late Mrs. Mary H. Pratt this institution is to receive the sum of $10,000.

Bequests to Hospitals.—St. Luke's Hospital and the Presbyterian Hospital of this city each are to receive $7,500 for the endowment of beds by the will of the late Mrs. Mary J. Johnson.

Traill County (N. D.) Medical Society.—At the recent annual meeting of this organization officers were elected as follows: *President*, Dr. McIntyre; *Vice-President*, Dr. Haagenson; *Secretary*, Dr. Anderson; *Treasurer*, Dr. Schanche.

Fifth District (S. D.) Medical Society.—At the meeting of this organization recently held in Sioux Falls, the following officers were elected: *President*, Dr. Hauge of Howard; *Vice-President*, Dr. Kaps of Winfred; *Secretary-Treasurer*, Dr. Frudenfeld of Madison; *Censor* for three years, Dr. Duff of Madison.

Hillsboro (N. H.) County Medical Society.—Officers as follows were elected at the annual meeting of this society, held at Nashua on February 7: *President*, Dr. George D. Lane of Manchester; *Vice-President*, Dr. A. S. Wallace of Nashua; *Secretary and Treasurer*, Dr. Ella Blaylock Atherton of Nashua.

Roosevelt Hospital Tax Decision.—The Supreme Court has decided in favor of Roosevelt Hospital against the city in the suit brought in its behalf to be relieved from $150,000 in taxes on property which it owns, but does not use for hospital purposes. The hospital has contended that its property was exempt from taxation under its charter granted in 1804.

In Memory of Pirogoff.—The twenty-fifth anniversary of the death of the Russian surgeon Pirogoff is to be commemorated by the founding of an invalid home for incapacitated physicians and a medical library.

Obituary Notes.—Dr. Adolph Kuhn of this city died on February 14 as the result of an attack of grip. He was born in Brooklyn in 1850 and was graduated from the Medical School of the University of New York in 1877. He served as interne in the Charity Hospital, and completed his medical education abroad. He made a specialty of diseases of the respiratory and circulatory systems, and held several hospital and dispensary positions. At the time of his death he was president of the West Side Taxpayers' Association.

Dr. William E. Kennedy of Muskegon, Mich., died on February 7, at the age of thirty-five years. After receiving a legal education, and being admitted

to the bar, he studied medicine, and was graduated from the medical department of the University of Michigan in the class of 1904. He had practised in Montague and Ravenna.

Dr. JOHN F. ENGLISH of Providence, R. I., died on February 9 of pneumonia, at the age of thirty-one years. He received his medical degree from the University of Vermont, and had practised for a time in his native city of Stafford City, Conn. He had been a resident of Providence for about a year and a half.

Dr. OMAR ROUTHIER of Lawrence, Mass., died on February 9 of pneumonia, at the age of forty-seven years. He was born in Cape Rouge near Quebec, and was graduated from the Montreal branch of the Laval University about fourteen years ago. He had practised in Lawrence since 1894.

Dr. HENRY A. GAFFNEY of Salem, Mass., died of heart disease on February 9. Dr. Gaffney was born in Charlottetown, P.E.I., in 1847, and, after graduating from St. Dunstan's College, received his medical degree from the Harvard Medical School in the class of 1870. Two years later he began practice in Salem, where he continued to reside until the time of his death. He was a fellow of the Royal College of Physicians of London, and had occupied numerous official positions.

Dr. CHARLES K. YANCEY, past assistant surgeon, U.S.N., died on February 10 in the Government Asylum for the Insane in Washington, D. C., at the age of fifty-nine years. He was born in Culpepper County, Va., and entered the naval service shortly after the close of the Civil War. His mind became deranged as the result of a period of duty in the tropics, and he had been an inmate of the Government Asylum for twenty-nine years.

Dr. WILLIAM H. DONNELLY of Worcester, Mass., died on February 8 as the result of a brain tumor, at the age of twenty-seven years. He was graduated from the Baltimore Medical College in 1905, and at the time of his death was house physician of the Providence Hospital in Holyoke.

Dr. JOSEPH MITCHELL of Lynn, Mass., died of apoplexy on February 7, at the age of fifty years. He was born in Oldtown, Me., and was a full-blooded Indian of the Penobscot tribe. He received his degree from the University of Ann Arbor, and was said to have been at one time a very successful practitioner.

Dr. L. S. CAMPBELL of Los Angeles, Cal., died on February 1, at the age of eighty-five years, as the result of a street car accident. He was born at Smyrna, Del., and received his professional degree from the Louisville College of Medicine in 1851. He first practised at Carmel, Ind., but in 1875 removed to Indianapolis. In 1901 he became a resident of Los Angeles.

Dr. JOHN B. STRACHN of Petersburg, Va., died on February 8, at the age of seventy-seven years. Dr. Strachn was a graduate of the Jefferson Medical College of Philadelphia, and had practised in Petersburg for about fifty years. He served through the Civil War as a surgeon in Rhodes's division, Stonewall Jackson's corps.

Dr. H. Z. GILL of Long Beach, Cal., died on February 6, at the age of seventy-six years. He was born in Buck's County, and was a graduate of Jefferson Medical College, Philadelphia.

Dr. JOHN BARKER of Woodbridge, Conn., died on February 16 of pleurisy, at the age of seventy-two years. He was graduated from the Yale Medical School with the class of 1860.

EIGHTH HARVEY SOCIETY LECTURE.

THE eighth regular lecture given this season under the auspices of the Harvey Society was delivered by Prof. Geo. S. Huntington, the well-known anatomist of Columbia University, at the Academy of Medicine, on Saturday, February 9. In introducing the speaker of the evening the presiding officer, Prof. Graham Lusk, spoke of the splendid anatomical school which had been built up by Prof. Huntington, and which was one of the very few schools in which highly important research work was systematically carried on. The subject of the evening's lecture would be "The Genetic Interpretation of Variations in the Genitourinary Tract."

The lecturer began by referring to the aims of the Harvey Society, and then said that the reason for choosing the topic he had was because it represented a field in which there had been real, rapid, and constant advances in recent years. He would endeavor to present the subject according to the following general scheme: (1) He would indicate briefly the more important facts in the development of the genitourinary system as it could be followed in the embryo. (2) Next he would point out the analogues of these phases as they were illustrated in the lower forms. (3) He would give illustrations of various anomalies as they were met with in the human subject.

The simplest type of a genitourinary system would, of course, be a perforation in the colon wall, so that the excretory products could find their way out, and the fertilizing cells have access to the generative cells. In the very earliest period of the life of the embryo there were two abdominal cords called the pronephron. These cords were straight tubes which, in the amphibia, served for both generative and urinary purposes. The speaker then went on to say that the original pronephron was very evanescent in vertebrates, lasting only a few weeks. It soon atrophied. Prof. Huntington next spoke of the development of the genital gland, and of the mesonephros. The latter persisted, so far as kidney function was concerned, in male and female amphibia. In the subsequent development of the mesonephros in male amphibia certain of the mesonephric tubules associated themselves with the sexual gland, converting the mesonephric duct into the vas deferens. In higher organisms certain structures were referable to the original mesonephric tubules, and were of interest as sometimes giving rise to the development of peculiar cysts and tumors.

The development of the duct of Müller was next touched upon. This duct usually developed as a tube parallel to the pronephric duct. It became the functional genital duct in the female type of higher forms. From it were developed the Fallopian tubes and uterus.

The speaker showed by means of diagrams how the early indifferent type could easily be developed into the higher amphibian type. In one case the Wolffian (or mesonephric) tubules connected with the genital gland—male, while in the other case these tubules were atrophied, and the Müllerian duct developed so as to be almost connected to the genital gland—female type. In either case this type could be developed still further, as in the mammalia, merely by the development of the permanent kidney as an outgrowth from the lower part of the mesonephric

duct. In this case, to be sure, the lower or urinary part of the Wolffian tubules atrophied.

The speaker then discussed the migration of the kidney and of the testes. The latter truly migrated; in the case of the former the migration was largely only apparent, due to unequal growth of tissues about the gland.

The room was then darkened and a magnificent series of lantern slides thrown on the screen. These showed preparations, made by Dr. Huntington, of a large number of animals, from the very low to the highest forms. Some of the slides were as follows:

Four pig embryos at different ages, showing in the youngest the enormous size of mesonephros. Lying behind this could be seen the permanent kidney. In the fully developed embryo very little was left of the mesonephros.

Iguana showed the condition brought about by retention of common mesonephroic duct opening into acloaca. It also showed two separate erectile organs, the analogues of the corpus spongiosum, but not fused into one structure.

A preparation of the python showed a similar condition.

In the turtle could be seen the fusion of the two erectile masses into one structure. The sexual duct, however, was merely a gutter along the margin of this, and not a true tube.

A preparation of the Virginia opossum showed the last remnant of the condition present in reptiles. In this animal there was a bilateral slit on the end of the penis.

The series continued through some of the higher mammals, and ended with preparations showing the carnivor types. This type was fairly common in the human subject, *e.g.* bifurcated kidney.

An interesting set of corrosion preparations of kidney anomalies was shown. Among these were double ureters, bifurcated ureters, etc.

Owing to the lateness of the hour the speaker was unable to take up the final part of the lecture, but invited all those interested to examine with him the series of preparations of human anomalies which had been collected for many years.

These were exquisitely mounted preparations, representing variations of all kinds. In some there was a persistence to a greater or less extent of structures originally present and developed beyond normal instead of atrophying. In others there was a failure of certain steps subsequent to the early development—as failure of certain structures to fuse, of certain septa to disappear, etc., etc. These anomalies were readily understood in the light of the foregoing developmental survey.

Tuberculosis of the Cecum.—Pauchet has been able to cure four cases of tuberculosis of the cecum, one by closed exclusion, another by exclusion treated secondarily by section, and two by resection followed by laterolateral anastomosis by the aid of a button. Tuberculosis in this region may show itself during the period of activity (ulcerative or caseous form) or after recovery, when it appears in the form of cicatrical lesions, hypertrophic or pseudoneoplastic conditions, or as a stenosis. The treatment suggested may be that of closed exclusion, which consists in isolating entirely or in part the large intestine; open exclusion in which a fistula is formed; or resection of the ileocecal segment with closure of the two extremities, and an ileocolic laterolateral anastomosis by the aid of a button. The incision practised is that of McBurney. The patients who have been operated upon have remained cured, one for six years, one for four years, and the last for four months. —*Revue de Chirurgie.*

Correspondence.

THE RADICAL CURE OF TRIGEMINAL NEURALGIA.

To the Editor of the Medical Record:

Sir:—So much needless suffering to a very unfortunate class of patients may be caused by the acceptance of such statements as are made in an article entitled the "Radical Cure of Trigeminal Neuralgia by Means of Peripheral Operations," by A. V. Moschcowitz, M.D., in your issue of February 16, that I venture to call the attention of your readers to the errors in that article.

(1) "We know nothing of the pathological anatomy of trigeminal neuralgia." This statement ignores the very complete and positive results published by Keen and Spiller in the *Amer. Jour. of Med. Sci.*, November, 1898, and subsequently confirmed by them, and by Thomas[1] of Paris in connection with his studies of neuralgia of the intercostal nerves—and also by Redlich[2] in his studies of tabes. The pathology of trigeminal neuralgia is known to be a degeneration with vacuolization and atrophy of the neurone bodies in the Gasserian ganglion, with secondary degeneration of their axones, and also a connective tissue inflammation in the ganglion, and also endarteritis in the small vessels within the ganglion. The same changes have been found in the spinal ganglia in intercostal neuralgia and in tabes.

(2) "All proof is lacking that the neuralgia originates in the Gasserian ganglion." There can be no better proof than the fact, of which I have personal experience in more than a dozen cases, that when operations upon the peripheral branches of the trigeminal nerve fail to relieve (as they always do fail to give permanent relief) an excision of the Gasserian ganglion or a division of the root of the fifth nerve between the ganglion and the pons always cures. I have never seen a relapse when the ganglion was completely and properly removed, and the published records of Hartley, who first did this operation in America, of Krause, who did it simultaneously in Germany, and of Keen, whose experience has been extraordinarily convincing in this line of work, amply confirm this conclusion.

These statements refute absolutely the other assertions of Dr. Moschcowitz, which therefore require no notice.

I have seen so many patients who have been operated upon in vain by various kinds of peripheral operations and recently by osmic acid injections into the nerve branches, and who have finally come to the radical operation after months of needless suffering, that I do not hesitate to recommend the operation for excision of the Gasserian ganglion, *provided I can select the surgeon to do it.* I have seen failures only in incompetent hands.

Dr. Moschcowitz claims that it is to the regeneration of the divided peripheral nerve that recurrence of pain is due. That may be true, but I have cases on my records where the pain has recurred after peripheral operation too soon to be due to regeneration; and other cases where it has recurred when a half-inch of the nerve has been exsected; and other cases in which pain has returned and at the radical operation no evidence of regeneration or union of the formerly divided peripheral branch has been found. Keen has similar records.

The cases cited by Dr. Moschcowitz are both too few in number and are reported far too soon to afford any convincing proof of his statements, but if his suggestions are followed patients will be only temporarily relieved, if at all.

M. Allen Starr, M.D.

AIR DISTENTION OF THE BLADDER.

To the Editor of the Medical Record:

Sir:—I hope you will pardon me for taking issue with you in regard to several of the inferences and conclusions given in the editorial on "Distention of the Bladder with Oxygen" (Medical Record, February 2). Taking them *seriatim:* It is asserted that Nitze attempted to use air in the bladder in connection with cystoscopic work, "but abandoned the practice because of the possibility of producing air embolism or of causing infection by germs carried into the viscus with the admitted air." Nitze did not abandon the use of air for the reasons named, but because (a) his cystoscope lamps were hot and would scorch the bladder wall if used with air; (b) the lenses of his cystoscope receiving a smear from the mucus of the urethra or bladder, would be put out of use. The claim of Lewin and Goldschmidt that the use of air in the bladder was dangerous because of the possibility of embolism was made later by several years

[1] Iconographie photographique de la Salpêtrière, 1902, Vol. XV.

[2] Redlich: Pathol. der Tabes, Jena, 1897

than the time of Nitze's attempted use of air; and the fallacy of the claims of Lewin and Goldschmidt has been demonstrated, during the last six or eight years, by the countless times in which it has been used without any such effect, and also by experimental demonstrations. Since practically all cystoscopes of the present day are supplied with lamps that are of low tension and without sufficient heat to cause discomfort even, the assertion that the injected oxygen does away with an objection to air on this score (that "the heat of the electric bulb of the cystoscope is also not found objectionable"), loses its apparent force.

While radiography for vesical calculi is interesting as a study, its value in the clinic does not compare with the more definite and satisfactory returns from cystoscopy in that condition; so that the quoted assertion of the authors of the use of oxygen, that it presents a distinct advantage in making radiographs "when the presence of calculi is suspected" is of questionable practical value. One thought suggested by the above is that if the conclusions of the authors are as much at variance with the actual conditions as their premises, their work promises little of value. However, this is to be determined by applying the oxygen to clinical uses.

Bransford Lewis, M.D.

St Louis, Mo

MEDICAL TREATMENT OF APPENDICITIS.

To the Editor of the Medical Record:

Sir:—Pfister's statistics on appendicitis treated with ice and opium, commented upon in the Medical Record of February 16, are in accordance with my own observations. Very many appendicitis patients will recover from single attacks, under ice and opium treatment—more in fact than will recover under unskilful surgical treatment. But are there not surgeons whose death rate in appendicitis is only one or two per cent., taking all classes of cases as they run, and refusing none? The fallacy in statistics like Pfister's lies in the fact that the report is incomplete. He does not tell us what happened to the patients in their subsequent attacks, or if they were where ice and opium treatment could be properly carried out by other physicians. He does not tell us how many of these patients suffered from gastrointestinal disorders of chronic character, due to peritoneal adhesions resulting from the infection. He does not tell us of the time wasted in bed by patients who would have been out promptly after nice surgical treatment. He does not tell us of the proportion of patients who may have post-operative ventral hernia, because of the kind of operation that may be required for complications in subsequent attacks—complications that would have been avoided by prompt and proper attention of the kind that is based upon sufficient data. I do not know how the German surgeons will accept Pfister's statistics, but in America they would be considered as unscientific and incomplete in character and mischievous in their influence. There are perhaps few surgical patients who are easier to save, or easier to lose, than appendicitis patients. Some time ago I published letters from ten consecutive appendicitis patients who had been operated upon, and who had had medical treatment in previous attacks. Every one of the patients stated that under surgical treatment they had suffered less than they did under medical treatment previously. Some of these patients had been treated by the ice and opium method. Pfister's statistics do not bring out points of this character.

616 Madison Avenue.

OUR LONDON LETTER

(From Our Special Correspondent.)

THE ORIGIN OF LIFE—TRAINING OF RECRUITS, DANGERS OF DRILL—CEREBROSPINAL MENINGITIS—OBITUARY.

London, February 1, 1907.

Those who take an interest in discussions on the Origin of Life may remember the part taken by Dr. Charlton Bastian in the early seventies, when he showed himself a stout controversialist and an experimenter. Since then his practical work as a clinical physician and teacher at University College and the National Hospital for Paralysis has brought him a great reputation, and his contributions on neurological subjects are highly esteemed. Probably you will agree with me that they are of more value than his speculations. He has, however, returned to his experimental investigations, and last week at the Medico-Chirurgical Society read a paper on the "*De Novo* Origin of Bacteria, Bacilli, Vibriones, Micrococci, Torulæ, and Moulds," in certain previously superheated saline solutions contained within hermetically sealed tubes. The solutions contained inorganical salts, and he said the best results were from two solutions—one having small quantities of sodium silicate, ammonium phosphate, and dilute phosphoric acid; the other, sodium silicate and liq. ferri pernit. With these solutions, he said, exposure to diffuse daylight at only 60° to 65° F. favored the appearance of microorganisms as much as darkness in an incubator at 95° F. The solutions were put in superheated tubes, sealed, and again heated to 239° F. and up to 266° F. for ten to twenty minutes. In all tubes after this a small deposit of silica or of iron silicate was thrown down. The tubes were then exposed to daylight or put in an incubator for periods of five weeks to four months. When opened he found in varying abundance one or more kinds of organisms, of which he showed photographs. No carbon was present in the solutions but its chemical ally silicon. Such solutions are nourishing media for organisms—can they engender the living units? was the question for the experimenter. After careful search Dr. Bastian said organisms were always found on or within the substance of the flakes of silica, while the fluid above was perfectly clear and remained so for months, though the organisms were swarming on the silica. Some were found in flakes taken from tubes from which all air had been expelled by boiling when they were hermetically sealed, so that no carbon could be present unless it had existed in the chemicals or distilled water. Even in tubes which did contain air this was always separated by a deep layer of the fluid itself from the deposit. As silicon replaces carbon in some organic chemicals, it was contended that these experiments give evidence that silicon may enter into the composition of protoplasm in place of carbon. As to the larger question of the origin of life, Dr. Bastian said that if the tubes were opened a few hours after heating no organisms were detected, but similar tubes, after longer exposure, contained them. They were always motionless, so had sprung up and multiplied in the sites where found. Dr. Bastian argued that they must have been engendered *de novo*, because, apart from spores of bacilli, no organisms could resist boiling for two or three minutes, and spores were killed by the same exposure to 239° F. The forms assumed he compared to crystals—regarding each as the resultant of the molecular constitution of their initial units on the particular media and surroundings in which they occurred. The lucidity of this explanation possibly your readers may appreciate.

Professor Starling lent a certain amount of support to Dr. Bastian's thesis, on the ground that inorganic material becomes organic in the body, and we call the change assimilation. Dextrorotatory sugars, he remarked, can be assimilated, but invert sugar cannot. But he could not deny that there was a great gulf between such assimilation and the production of new life. If it be maintained that higher forms of life are continuously evolved from lower forms, the process might not stop at the lowest, and it seemed natural to seek for a bridge to span the gulf that separates the living from the non-living. Even in the body the red blood cells were on the border line, and when killed by formalin gave reactions which were considered characteristic of living cells. In the fortuitous concourse of atoms it might be supposed that a substance capable of growth might occur, and, if it had stability enough, acquire a power of adaptation to environment indistinguishable from living protoplasm. Even then it would only be the pabulum for more highly organized bodies, and it could only survive under such conditions as Dr. Bastian's tubes provided. The practical question was whether the bodies found in these experiments were really alive. He did not admit that this was proved. A plate culture would be some evidence, but cultivation would have to be under the same conditions as those under which the organisms had been formed.

Dr. F. W. Goodall said he did not feel satisfied that the tubes had been perfectly sterilized, nor that the motionless bodies exhibited were actually alive. How could their life be recognized?

Dr. Bastian replied that his tubes were subjected to a very high temperature and, after being filled, exposed further to 266° F. for twenty minutes, which would certainly kill all organisms and spores. In the tubes opened in a few days nothing could be found, but in those examined later organisms swarmed in every drop. They not only increased in the tubes, but multiplied under suitable conditions after removal to a slide. Some were unlike any hitherto described.

At the Royal United Service Institution, on Wednesday, Lt.-Col. F. A. Davy, M.D., late of the Army Medical Corps, brought a grave indictment against the methods of training recruits. Surgeon-General T. J. Gallway, P.M.O., of the Aldershot Army Corps, presided, and an interesting discussion took place. Col. Davy regarded the setting-up drill of recruits as a main cause of diseases of the circulatory system and the invaliding of many soldiers. Mechanical obstruction and strain were imposed on the heart. There ought to be nothing in drill that would not benefit even a defective man, but the system of military drill in vogue

was injurious to the strongest, and was training with a blot in it. The measurement of the recruit's chest might be increased by it, but only at the expense of motility and of vital capacity. Sooner or later it became distressing—exhaustion after morning drill indicating danger. Col. Davy was sure that in the majority of men invalided for heart disease—excluding rheumatic cases—the early link in the pathological chain was forged on the drill ground. Before appearing at the hospital there would be a long period of discomfort, heart beating, dyspnea, etc., for which the young soldier blamed his recently-donned pack or valise, forgetting that before enlisting he could have carried it easily enough. Tight clothing was bad, but the attitude was worse. The result of keeping expiration in abeyance was a disturbance of the balance between pulmonary and systemic circulations. The chest swelling adopted by drill sergeants must be followed by injury, for it was in contravention of physical laws. The evil was greater because it was done in the name of good. It produced deserters as well as invalids. What was often called fine physique was really deformity. He held that this chest swelling was contributing largely to the waste of the army. The remedy was easy—merely to abstain from chest dilatation, from directing the forepart of the feet to bear the weight of the body and movements designed to "open the chest." Col. Pollock, at Hounslow, used no breathing exercises.

Col. Rolt, Inspector of Gymnasium, hinted that the author was not quite up to date, as the army council lately adopted a system based on the Swedish, which, he thought, Col Davy would approve. The drill book was to be altered accordingly.

Col. G. M. Fox said in his experience soldiers did not "blow themselves out" except at inspections. Deep inspirations and expirations kept up the motility of the chest.

Dr. Deane thought the position of "Attention!" was neither esthetic nor useful. The natural position of a man was erectness without rigidity. He thought the Army Gymnastic Staff should have charge of drilling, under the superintendence of the Army Medical Corps.

Maj. Moore said Col. Pollock's company were all picked men and superior to the ordinary recruits, both physically and intellectually, so his success proved nothing. He thought Col. Davy had pointed out the blot on the system. The root of the evil was hurrying the training too much.

General Sir J. Moody said he never knew men in the marines to suffer from the effects of setting-up drill.

Cerebrospinal meningitis is causing some deaths. At Glasgow the Health Office reports that thirty-three cases were notified during January, and that seventeen proved fatal. The disease seems making headway among children, and has been placed under those notifiable. At Leith two deaths have been registered, one on January 15, the other on January 29. One of these occurred in the Leith Hospital. The M.O.H. has had the houses of the patients disinfected and taken all precautions. The man who died on the 29th had been working in Leith Docks on a steamer which had arrived from America. Notification has not yet been made compulsory at Leith.

The death of Sir Michael Foster, which took place rather unexpectedly on Tuesday, while on a visit to London, deprives us of a leading physiologist closely identified with the profession. He was a University College student, whence he graduated B.A. and M.D. at the University of London. For five or six years he practised at Huntingdon, where he was born in 1836, his father being a surgeon in the town. In 1867 his college made him Demonstrator, and two years later Professor of Physiology. In 1870 he went to Cambridge as Prælector at Trinity College, where he became a Fellow. In 1883 the University gave him the professorship. Soon after entering Trinity he was elected F.R.S., and in 1881 he was appointed secretary in succession to Huxley, who became president. He was knighted in 1899, and the next year entered Parliament as representative of the London University. He rather disappointed his supporters there, though on some subjects he was listened to with close attention. He was elected as a Liberal Unionist, but when the Fiscal controversy arose he ranged himself with the Free Fooders, and after a time crossed the House to the Liberal side. At the last election he lost his seat.

Mr. C. J. Oldham, F.R.C.S., Surgeon to Brighton and Sussex Eye Hospital, died on January 24, aged fifty. He was a Guys student and served in the several resident posts at that hospital and then became clinical assistant at Moorfield's and Assistant Surgeon to the Central Ophthalmic Hospital. At the International Ophthalmological Congress, in London, in 1872, he read a paper on an improved refracting ophthalmoscope, and demonstrated its value. He was then settled at Hove, Brighton, where his skill as an oculist had secured him a large practice. Outside his profession his hobby was music and the collection of rare violins.

The late Dr. Savage, who was killed in the earthquake at Jamaica, had since his retirement made several trips to the West Indies. In a long and active career at Birmingham he had reaped abundant success and distinction. He was Surgeon to the Hospital for Women from its foundation, had been lecturer at Sydenham College and Queen's College. At the latter he held the Chair of Midwifery, and on it merging in the University of Birmingham he was made the first professor of the subject, his colleague at the Women's Hospital taking the professorship of Gynecology. Dr. Savage was also Consulting Surgeon to Hospitals at Wolverhampton and Kidderminster, and had been President of the British Gynecological Society. His Ingleby lectures on "Abdominal Section," in 1881, and his papers on "Uterine Myoma," and other points in the specialty, are worth notice, though his practical skill and success as a Surgeon in the department overshadow his literary contributions. He was M.D., S.L., A.M., 1862; F.R.C.S., 1860. Later he joined the College of Physicians. He was also F.R.S. Eden, and became a J.P. and a County Councillor for Warwickshire.

OUR BERLIN LETTER.

(From Our Special Correspondent.)

CARCINOMA OF THE APPENDIX—A NEW HEART DRUG—CRIPPLES IN GERMANY—HAY FEVER—GOITER—INCREASED FEES FOR MEDICAL MEN—BIRTHDAYS OF BERGMANN AND WALDEYER.

BERLIN, January 10, 1907.

A PAPER on primary carcinoma of the appendix was read recently by Landau before the Medizinische Gesellschaft. In performing a hysterectomy for myoma of the uterus the appendix was found thickened at one point and it was accordingly removed. Microscopical investigation showed that a carcinoma simplex was present. The speaker said that he had been able to find records in the literature of only fifty-eight such cases, and that in a quarter of these the tumor was not diagnosticated before autopsy. In 50-60 per cent. of all cases the new growth originated in the tip of the appendix, and women were more frequently involved than men. The age of the patients varied from eight to eighty-one years, though most of them were between forty and fifty. The symptoms were the same as those of a simple appendicitis, though the pain had a tendency to be dull rather than acute. Only in six cases has surgical intervention been carried out on this account, the organ usually being extirpated because it was discovered to be diseased in the course of other operations.

A remedy which may possibly be found of use as a substitute for digitalis always merits the interest of physicians. Such a remedy, found in the *Acokanthera schimperi*, was described by Lewin in a paper read before the same society. In 1888 there was obtained from an arrow poison named onabai, a crystalline glucoside, which was called ouabain. Recently the speaker had been able to isolate from the leaves of the akocanthera an amorphous glucoside ouabain which had the same composition as the crystalline form, but possessed greater influence on the heart. The effect of ouabain was a hundred times stronger than that of digitalis, and a rhinoceros could be killed in twenty minutes by an amount equal in size to a bean. The glucoside slowed the pulse and increased the heart action, the systolic impulse being more powerful and causing a better filling of the vessels. In a dog weighing twelve kilograms the injection of 1 millogram of ouabain caused the blood pressure to rise from 153 to 213 mm of mercury.

A short time ago the first Berlin Orthopedic Hospital was opened. The building contains only ten beds, but it is expected that this number will soon be increased. In his opening address the director, Dr. Biesalski, pointed out the importance, from the economic standpoint, of a proper system of caring for cripples. In Germany there are about twenty institutions of this sort, though not all are under medical control. The statistics of the institution for crippled children in Munich show that during the past seventy five years 93 per cent of the children treated have been enabled to earn their own living. In Berlin the last enumeration of the crippled showed that there were 2,700. Assuming that the total for Germany is 100,000, it may be estimated that if proper measures were taken 90,000 persons now more or less dependent on outside aid could be made capable of earning their living.

A paper on pollen endotoxin was presented by Wolff before the Verein fur innere Medizin. He said that hay fever began a fortnight sooner than usual this year on account of the early spring. The serum treatment succeeded in mild cases, and in those of medium gravity, but was without success in very severe ones. The speaker further stated that the affection was much more widespread than was generally believed, because many cases of rhinitis were caused by pollen, and, therefore, diagnostic inoculations with pollen antitoxin were of importance, especially for army physicians. As prophylactic measures he recommend-

ed packing the nose with absorbent cotton or some other form of filter for the air entering the nostrils. As the conjunctivæ were often the starting point of the affection, the wearing of eye glasses surrounded by a padding of cotton was advisable.

Hildebrand, at a recent session of the Medizinische Gesellschaft, reported his observations on goiter and its treatment. He pointed out that it was not always the largest tumors that caused the greatest disturbances. Growths extending under the sternum and under the ribs could easily compress the lungs and large blood-vessels. The external application of iodine was not successful, and its internal use was effective only in recent cases of follicular goiter. In older persons operation was the only remedy. Injections of iodoform were not without danger, they did not entirely relieve the patient, and rendered succeeding operations more difficult. The operation was much facilitated by using local anesthesia, Kocher's method of skin dissection, and preliminary ligation of the blood-vessels. Performed in this way the mortality of the operation was .3 to .5 per cent. The prognosis of malignant disease of the thyroid gland was particularly bad, for thrombosis of the veins occurred early. Out of thirty cases the speaker had had only one remain free from recurrence for a year.

The medical societies have united in taking a step which the exigencies of modern life have rendered imperative. For half a century the honorarium of the physician has remained the same, although the expenses of living have increased greatly. The medical societies have, therefore, announced that with the beginning of this year fees for medical services would be increased.

The past months have shown that Berlin is not lacking in evidences of appreciation of its great medical men. On the occasion of Waldeyer's and Bergmann's seventieth birthdays a celebration was held which was participated in by the members of the University and a large number of physicians. The practitioners especially owe much of their satisfactory standing to Bergmann's efforts. His merits as a surgeon are well known, and I will say only that much of his most important work was done in the province of military medicine. In 1807 he founded the Berliner Rettungsgesellschaft, an organization intended to give first aid in cases of accident. He also established a bureau for the providing of adequate nursing and medical treatment for the poor in their homes. In 1899 he was elected a member of the Aerztekammer, and he rarely misses a session. It was through him that the present free courses for postgraduate study were organized, and the erection of the splendid new Kaiserin Frederich Haus was also largely due to his efforts.

OUR CONSTANTINOPLE LETTER.

(From Our Special Correspondent.)

THE RUSSIAN HOSPITAL AND ITS CHIEF, DR. VLADIMIR STCHÉPOTIEW.

CONSTANTINOPLE, January 8, 1907.

ONE of the most interesting and most admirably equipped charitable institutions of the Ottoman metropolis is undoubtedly the Russian hospital. Its chief, Dr. Vladimir Stchépotiew, has been kind enough to conduct me through all its various departments, wards, laboratories, surgical rooms, etc., showing and explaining things with that untiring sympathetic affability which is characteristic of almost every educated Russian gentleman. Dr. Stchépotiew is quite naturally very proud of his hospital, because it is, in all its present working order and efficiency, entirely his creation. During the sixteen years of his administration of it many important improvements have been accomplished, many innovations introduced, many modern essentials added. All has been done step by step with much judicious care and circumspection, with unabated energy and generous though wise expenditure of money, until the charitable institution has become, what it is now, an up-to-date model of a hospital establishment, with all the latest requirements of medical science.

Not without particular interest is the history of the origin of this establishment. The first foundations of a Russian hospital in Constantinople were created about 1869 by the then Russian Ambassador, General-Adjutant Count Ignatiew. He was the first to recognize early the necessity of an infirmary on the banks of the Bosphorus for the large numbers of people of Slavonic nationalities, such as the inhabitants of Macedonia, Albania, Montenegro, Bulgaria, Russia, etc., who continually pass through and flock to the magnificent metropolis on the ever-inexhaustible, mighty Thracian stream. In the mentioned year Count Ignatiew opened, with the sanction of the Russian Government, in Russia as well as among the Russian subjects resident in the Ottoman Empire, subscription lists to gather contributions for his hospital scheme. In the course of four years the free offerings amounted to 39,000 roubles (something about $15,000). In the beginning the Russian Ambassador experienced some difficulty in obtaining proper grounds for the building, as the greater part of land in Constantinople and in other parts of Turkey is so-called "vakouf" property, that is to say, it belongs to mosques and Mussulman religious institutions, is therefore sacred, and must not be sold to Europeans. The original piece of ground bought by Count Ignatiew happened to adjoin a "tekke" (Mahomedan monastery). The Turkish Government, in consequence of that, objected to the erection of a hospital on that place, and bought it up for 5,000 Turkish liras (about $20,000). Other grounds were bought, more appropriate and extensive, where the first buildings of the hospital were erected. Soon afterward, in 1873, the Emperor Alexander II sanctioned a grant for the Russian hospital to the amount of 130,000 francs. A committee was there and then appointed under the presidency of Count Ignatiew, the Ambassador, to establish rules and regulations concerning the administration and management of the hospital. The following points in these rules and regulations are of general interest. The hospital, which is dedicated to Saint Nicolaus, is to be under the direct patronage of the Russian Ambassador. The administration is entrusted to a committee consisting of the Russian Consul-General, the chief physician of the hospital (at present Dr. V. Stchépotiew), the doctor of the Embassy, and a secretary appointed by the Ambassador. The committee has to meet once a month. The hospital is open to everybody regardless of nationality. Preference, however, is given to Russian subjects and to Slavs. Everything concerning the medical management is under the direct supervision of the chief. . . . The present three-story building of massive stone was erected in 1875 by the means of Mr. Shabouroff, who some time previously gained from the Turks, through the assistance of the Russian Embassy, a very big lawsuit. The then living Princess Alexandra Petrowna took the hospital under her patronage and made a generous offering to it of all the necessary linen, crockery, and bed-covers. She also ordered that Russian sisters of charity should be sent to the hospital to attend to the patients. In 1876 an *ukase* was issued that certain taxes should be levied in aid of the Russian hospital from every commercial sailing vessel and steamer passing through the Bosphorus and from every passport of Russian subjects coming to Turkey. All the poor, however, are exempt from this tax. In 1889 the committee of the hospital found it necessary to create the post of a chief medical administrator, which should be free and independent, and in the following year Dr. Vladimir Stchépotiew, then working with Professor A. A. Ostroumoff in the university of Moscow, was called to fill this important post. He has held it now, as already mentioned, for sixteen years, with admirable skill and energy.

The buildings of the hospital proper, with all the adjoining constructions, which are quite numerous, occupy an excellent position in the most salubrious district of Constantinople called Pancaldi, on an elevation of 300 feet above the sea level. From the windows of the chief building a magnificent view unfolds before one's eyes. A broad, extensive, ever-green valley stretches down to the deep and pure current of the Bosphorus. Beyond are seen the famous Scutari cypress woods, the Marmora Sea, and further still, on the very horizon, the so-called Princess Islands, summer resorts of the well-to-do inhabitants of the Ottoman metropolis. Not far from the hospital is the quarter Nishan-Tash, where are the residences of the Grand Vizir, ministers of State, and dignitaries of Yildiz-Kiosk. The extensive grounds of the hospital include two gardens and twelve different buildings: the infirmary proper, the houses of the chief medical man and his assistant, an ambulatory, a house for the care-taker, a beautiful church, a house for the priest and his assistants, a post-mortem room, a separate building for servants, a laundry, a Turkish bath, and a separate house for venereal cases. There is also a spacious terrace which is joined to the principal building of the hospital by a covered glass gallery. On this terrace patients with chest troubles are able to promenade in suitable weather, breathe the fresh air from the Pontus, and enjoy a magnificent view of the scenery around. There is on it also a veranda which shelters from the cold north winds. Here spend a greater part of the day such patients as need much pure out-door air. The principal building is, as already mentioned, of stone and consists of three stories. In each story there runs in the middle from one end to the other a broad corridor well ventilated and with plenty of air and light. In the lower story there are a large dispensary and a laboratory. The second floor contains excellent operating rooms with all the modern requirements of surgical science, four large rooms for paying patients, where one receives the best

possible treatment for forty piasters daily (about $2); the reception room of Dr. Stchépotiew, apartments for the sisters of charity, and a bath room. In the third floor there are five chambers for paying patients, and the wards, with thirty-three beds for free patients. The kitchen is in a separate building. On every floor there is a large filter apparatus supplying, under pressure, quantities of pure drinking water. The heating is done with stoves more or less resembling those seen in Holland, with the only difference that they contain inside iron tubes. For more efficient ventilation the windows are provided with frames of the system of the Swedish authority, Dr. Chastaing. This system consists in two parallel panes inserted in the upper part of the window frame at a small distance one from another, and in a manner that the outer pane leaves below and the inner one leaves above an open space of two centimeters breadth. In this way the outer air has free communication with the inner without creating any draught. The hospital is provided with a thermo-syphon, which provides in each story a constant supply of hot water. All the rooms and corridors are oil painted.

The staff of the hospital consists of two medical men, the chief and his assistant, six sisters of charity, a general medical assistant, and a care-taker. There are also eleven servants. For difficult surgical operations the services of Dr. Cambouroglou Pasha, chief of the surgical department of the German hospital, are secured. From 1881 to 1887 the annual number of patients treated in the wards did not exceed 300. From 1893 to 1899 the number was over 400. For the last five years the average has been 350. The average annual number of patients received in the ambulatory was in the last few years over 11,000. All these patients were treated and supplied with the necessary drugs free of charge. The out-patient department of the Russian hospital is the most frequented. The numbers are constantly increasing, and reached last year to about 13,000. The greatest number of natives consist of Turks, Greeks, and Armenians. The hospital patients are mostly Russians, Bulgarians, Servians, and other Slavs, and many Jews. Some years ago a charitable fund was created for the purpose of helping the poor patients on their leaving the hospital after being cured. Contributions are received mostly from Russian subjects serving in Constantinople. At present the fund has a little over 2,200 roubles. The diseases treated are generally typhoid fever, pneumonia, articular rheumatism, and consumption. The yearly statistics show that, generally speaking, the following five classes of people form the largest contingent of those received into the hospital: Laborers, sailors, gardeners, servants, and monks. As already indicated, every credit is due to Dr. Vladimir Stchépotiew's energy and administrative wisdom and circumspection, as the perfect state of the Russian hospital, as it is seen and admired at present, is entirely his work. Mention should be made also of the valuable efforts of the Russian Consul-General, Mr. Panaffidine, whose wife is an American lady, who does all in his power to advance the prosperity of the hospital.

OUR LETTER FROM THE PHILIPPINES.

(From Our Special Correspondent.)

APPROPRIATIONS FOR NEW HOSPITALS—SANITARY IMPROVEMENTS AT BILIBID PRISON—TEMPORARY NATURE OF WOODEN BUILDINGS—CHOLERA—A POSSIBLE EXPLANATION OF PERIODICAL OUTBREAKS—PERSONAL.

MANILA, P. I., December 31, 1906.

THE activity of the Bureau of Health in keeping before the public the inadequacy of the present hospital facilities in Manila and the great need for additional quarters for the care of the sick has at last received concrete recognition in a recent appropriation bill of the Philippine Commission. Fifty thousand dollars were appropriated for a new hospital at Bilibid Prison; ten thousand for the installation of a proper sewer system and toilet facilities, and ten thousand for the installation of sanitary beds, instead of the present miserable vermin-ridden bamboo bunks; and twenty-five thousand for the construction of an addition to the present San Lazaro Insane Hospital.

The hospital at Bilibid will consist of an administration building with two wings, one for the care of tuberculous prisoners and the other wing for general diseases. It is also the intention to send at least 1,000 prisoners to the penal settlement on the island of Palawan. With the improved hygienic conditions which will result from the above mentioned changes, it is thought that the morbidity and mortality among the prisoners will be materially decreased.

With the addition to the insane hospital at San Lazaro that institution will then be able to care for 350 insane, which will relieve, at least to a certain extent, the pressing appeals which are constantly being made on behalf of these unfortunates.

The material for the construction of the insane hospital is to be of reinforced concrete, which will make a permanent structure and one that will not suffer very much from deterioration. The experience which the Government has had since the American occupation in the construction of buildings has been sufficient to show that structures of Oregon pine, red wood, or other soft wood are most temporary in character, the destructive influences of a tropical climate causing their complete deterioration in a few years. The white ant is probably responsible for most of the damage, and is a pest which it is difficult to guard against, because it enters a building through small tunnels and never works in the open. Very often its presence is not detected until the building collapses, when it is found that nothing remains but a shell of wood, the entire core or pulp having been eaten out. Dry rot is another important factor in the early decay of wooden structures; so that, while a stone and cement structure costs more in the beginning, it is very much cheaper in the end. Many of the army posts throughout the island, which were constructed during the early days of American occupation, have been entirely destroyed by the white ant. There are also numerous other forms of animal borers that shorten the life of wooden structures.

Cholera seems to have almost entirely disappeared from the island of Luzon; in fact, there is very little remaining anywhere in the Philippines. For the week ended December 22, 1906, fifteen cases and six deaths were reported in the province of Capiz, on the island of Panay, and four cases with four deaths in Oriental Negroes. This would indicate that the epidemic is about to terminate. The disease has been reported at a number of places, but upon investigation it was found that the victims had partaken of large quantities of green rice. According to native physicians many deaths occur yearly in the Philippines from this cause. The fact that there has been no spread from these suspicious cases would seem to indicate that the diagnosis of rice poisoning was correct

Since Kline's announcement that plague organisms probably show different degrees of virulence, depending upon the condition of the envelope which surrounds the organism, considerable speculation has been indulged in, in the Philippine Islands, as to whether the periodical outbreaks of cholera, and, in some instances, its rapid disappearance, cannot be accounted for upon the same theory. It would seem possible that certain weather conditions and an environment favorable to changing the character of the envelope which might surround the cholera organism would probably account for the cholera which has been encountered in the Philippines during the last six months.

So far there has been no official report made by the committee appointed by the Governor-General for the purpose of investigating the responsibility for the deaths of the prisoners in Bilibid Prison, who were inoculated for cholera protection, and of which mention has been made from time to time. It is known, however, that of the twenty-four prisoners inoculated thirteen have succumbed, and that there are a number of others who are in a very precarious condition.

Dr. Jos. B. Girard, Colonel, Medical Department, U. S. Army, who has been Chief Surgeon, Philippines Division, for the past few years, has completed his tour of duty in the islands and returned to the United States on the Army transport which left December 15, 1906.

Dr. Charles B. Byrne, who has been Chief Surgeon of the Department of Luzon, was made Chief Surgeon, Philippine Division, on the departure of Col. Girard.

Dr. Wm. H. Cook, Contract Surgeon, U. S. Army, recently stationed at Camp Bean, Samar, and who was formerly a medical inspector of the Bureau of Health, has returned to the United States.

Dr. F. W. Dudley, Assistant Surgeon, St. Paul's Hospital, Manila, has returned to the Philippines after an extended visit to the United States.

Determining the Sex of the Fetus.—In regard to this Sheill says that "a still tongue makes a wise head," but gives the following as the result of his own observations. The rule followed was that if the fetal heart rate is 141 or less, the child will be a boy; if it is 147 or more, a girl; and if between these two limits the sex is doubtful. In 300 cases the prediction was correct in 56 per cent; omitting those cases in which the women were already in labor the percentage of correct predictions was 73; while counting only primiparas mistakes were made altogether in not more than one-tenth of the cases.—*Dublin Journal of Medical Science.*

Progress of Medical Science.

New York Medical Journal, February 9, 1907.

The Scranton Typhoid Epidemic.—J. M. Wainwright presents a preliminary communication on this subject. Up to January 31, a period of nearly two months of the epidemic, 1,121 cases had been reported, with a mortality of about 9 per cent. The epidemic is now on the decline, only four new daily cases having recently been reported. The direct source of the outbreak was an infected water supply, but what infected it has failed to come to light after a most rigid investigation. The outbreak was practically confined to persons using water from a particular reservoir, and to those in personal contact with such cases. The principal supplying stream of the reservoir receives a few miles above the sewage of a town of some eight hundred people. The city has had in past years comparatively little of the disease. The cutting out of the water supply from the infected reservoir from the general city water mains broke the force of the epidemic at once. The author details the special municipal and household regulations which were instituted. Nothing is stated concerning any peculiar clinical features of the outbreak. He pays a handsome tribute to the Mayor of the city, who seems to have been all that a municipal executive should be in such an emergency. We are told that "it is in a very large degree to his singleness of purpose, breadth of view, and ability for organization that scores of cases and many deaths have been prevented and only those who have worked with him will ever know the debt which his city owes him."

Etiological Factors of Invalidism Following Childbirth.—Some of these factors are reviewed by J. C. Applegate. Predisposing factors are lack of knowledge on the part of the laity as to the importance of hygienic measures and inattention on the part of the physician not especially interested in obstetrics as to the position of the child, pelvic mensuration, and the effect of pregnancy on the maternal organism. Factors during labor are the influence of posture on mechanism, the modifying effect on injuries to the birth canal by anesthesia, protection of the perineum during the birth of the shoulders as well as of the head, and instrumental delivery. Post partum factors are time for repair, method of repair, no repair at all, and the general management of this period. The paper is an elaboration of the above outlines. Concerning repair, the author follows the following rules: (a) Immediate repair when convinced from the primary examination that the lesion involves the perineum alone, or the tissues in immediate juxtaposition thereto, when the patient's condition will warrant it, excepting the complete variety. (b) When deep vaginal or cervical lacerations demand immediate repair to control hemorrhage, otherwise the cavities are packed with gauze and operation deferred. The second day rather than a later period is selected for the complete tear or when fistulæ are complications, at which time all lesions are repaired from above downward. The condition of the patient will rarely permit these operations at the end of labor, nor is the physician prepared for them. While this is not the best time for cervical repair, it is better than at the end of labor, also better than to subject a patient to the second operation during the puerperium.

Atypical Manifestations of Paludism.—Ten atypical cases are detailed by J. I. France of Portsmouth, Va. He concludes: First—That chill, fever, and sweating are not always the mode of onset of malarial infection. Secondly That the seat of pathological change or congenital defect is often the point of attack of plasmodial invasion. Thirdly—That periodicity is the one pathognomonic symptom of all forms of paludal infection. Fourthly—That women are oftener the victims of malarial infection than men. Fifthly—That quinine is the standard remedy for malaria. He also notes that tissues which have undergone pathological changes and those which are congenitally defective are more susceptible to the toxine, which is elaborated in the process of segmentation of the hematozoa. What the factors are which determine the variation in the mode of manifestation of this toxemia, so that in one patient it takes the form of a febrile reaction, in another a painful paroxysm, or a seizure of some sort in an organ previously crippled by disease or congenitally defective, are at present not fully determined, but the fact is fully attested by ample clinical observation.

Journal of the American Medical Association, February 16, 1907.

Late Phlebitis After Clean Abdominal Operations.—W. W. Grant says that he has been compelled by later observations and experience to modify his formerly expressed opinion that phlebitis after abdominal, rectal, or genitourinary operations is invariably due to infection. In his paper he considers especially that form of phlebitis culminating in the veins of the legs (usually the left leg), and occurring most frequently about two weeks after simple aseptic abdominal operations, without preceding fast pulse, fever, pain, or any other premonition. He refers to the statistics of Cordier and Haward and gives the account of a typical case occurring after operation for chronic appendicitis. He asks what was the etiology of this phlebitis, and gives a summary of the literature of the subject as well as the opinions obtained by correspondence with a number of prominent surgeons. These vary somewhat, nearly half of the answers admitting infection as a possible cause, the others rejecting it or being noncommittal. Grant gives his own opinion that it is probably not septic, and that the specific cause or causes are unknown. It is not correct, he thinks, to assume an infection without satisfactory evidence. The cause of the thrombus before the inflammation or of the phlebitis preceding the thrombus, is the vital point. It is impossible, Grant says, to reconcile the facts with the idea that the cause is the recumbent position or the simple ligature or injury of small veins, often in a distant field and on the opposite side of the body, though admitting that the infection need not come from the site of the operation. He believes that there is a general condition affecting the composition of the blood, that may, and often does, exist before operation, which is an essential factor in the cause of the thrombophlebitis in these cases. A careful scrutiny of the patient should be a preliminary and a careful examination of the blood should be made before and after operation. This, if thoroughly done on a fairly liberal scale, would, he thinks, give us interesting and useful information and throw some light on a puzzling subject.

Opsonic Treatment of Surgical Diseases.—A. P. Ohlmacher thinks that possibly Wright's comparatively simple theory of opsonins and its practical application has been rendered needlessly confusing to the average practitioner, and gives his own experience with the use of bacterial vaccines, preferably autogenous, in various surgical conditions. While not neglecting to take the opsonic index when practicable, he was compelled to rely largely on the clinical manifestations as a guide to the repetition and size of dose, always endeavoring, of course, to give the injections at the right time, when the positive phase is beginning to fall, and not in the negative phase. As Wright points out, the great causes of failure in previous tuberculin treatment was the giving of too large injections and too frequent repetition of the dose, causing a marked negative phase and keeping it up. Ohlmacher thinks that his results might have been even better than they were had he been able to make more systematic opsonic determinations, which often show a fall of resistance before the symptoms indicate it. He has had remarkable success in various types of staphylococcus infections; obstinate cases of acne and furunculosis, impetigo, palmar abscess, and in a very distressing case of what had been called psoriasis, but which he thinks was an extraordinary case of staphylococcic dermatitis, and which yielded rapidly to opsonic treatment with an autogenic culture of staphylococcus aureus. He had also satisfactory results with a case of very annoying bladder infection from the colon bacillus, similarly treated after other treatment had failed. A striking case was one of sacculated pneumococcus empyema, in which perfect recovery occurred in seven days after two injections following a small puncture. From what he has already seen, he is prepared to say that with proper artificial autoinoculation, we can obtain constitutional and local improvement in many subacute and chronic affections entirely beyond anything previously possible in medicine. He believes that we have in this method of bacterial inoculations therapeutic agents of a specificity and potency beyond anything heretofore employed in the treatment of disease, except, perhaps, the diphtheria antitoxin.

The Army Canteen.—C. E. Woodruff advocates the restoration of the Army canteen as a protection or counteraction against the grog shops that grow up around an Army post and entice the soldiers into excess. He maintains that while the soldiers are as temperate as any class of laboring men at the present time, and have the advantage of being less neurotic

as a rule, there are still many that will not be total abstainers, and for these, he says, it is better to have a regulated and orderly place, where they can obtain the milder intoxicants, such as beer and light wines, rather than to have them obtain them at disreputable places, run for profit, and that cannot be controlled. It is good ethics, he says, to protect the soldiers from the greater evil by permission, it may be, of a minimum of harm. The profits of the canteen, moreover, are not to the saloonkeeper, but are used for the benefit of the soldier himself. The discontinuance of the canteen has, therefore, been to the soldier's disadvantage on this account. He further argues that the moderate use of alcohol cannot be said to be necessarily harmful on scientific grounds, though that is not claiming that it is a necessary article of diet in the present stage of human evolution.

X-Ray Treatment of Cancer of the Breast.—George C. Johnston criticises some of the reports of failures in this method of treatment as being based on ignorance and insufficient experience. He insists on the value of what he calls antioperative radiation, and claims that during the past year there has been abundant evidence of the value of the ray in producing retrograde change in carcinoma, but advocates the use of the ray alone only in cases in which the condition or age of the patient is against preliminary operation. His conclusions are given as follows: 1. Results are better and more permanent, the earlier the treatment is instituted. 2. The value of postoperative radiation has become more and more apparent. 3. Mediastinal recurrence, while grave is not a death warrant. 4. Technique is not an accomplishment, but an absolute necessity. 5. No tube is too good to use for treatment. 6. Filters are a necessity in the treatment of cancer of the breast. 7. Treat no patient who you know can be cured surgically.

Mistakes in the Diagnosis of Pulmonary Tuberculosis.—H. L. Barnes gives an analysis of the histories of 165 patients with tuberculosis admitted at the Rhode Island State Sanatorium for Consumptives, with special reference to the question of early diagnosis and treatment. Only the cases with reliable and complete record were used. He found the presumable duration of the disease averaged 15.4 months, and that 40.9 per cent. of the patients delayed seeking medical advice or treatment, such delay averaging 7.9 months. Forty-six per cent. were incorrectly diagnosed, the resulting delay in correct diagnosis averaging 11.3 months. In 18.1 per cent. of patients the lungs were examined and pronounced sound; and in 18.7 per cent. the incorrect diagnosis was made without sputum examination, though sputum was available. In 2.4 per cent. the correct diagnosis was purposely withheld by the examining physician. Barnes regrets that this practice is still followed by some, and holds that it is not warranted by any valid considerations. The failure to diagnose tuberculosis after hemoptysis also is surprisingly common, occurring in 12.7 per cent. of the cases here analyzed. Inasmuch as the sanatorium does not receive the worst cases, it seems possible that those it does receive have been more wisely handled than the average of all tuberculous patients in the community, which gives figures an added significance. He says: "This optimistic and fatal waiting policy should be appreciated. A tuberculous history should be sought for in all lung diseases, and in atypical and doubtful cases of grippe, bronchitis, and malaria the diagnosis should promptly be made by tuberculin when other means fail."

The Lancet, February 2, 1907.

Hematuria from Sodium Salicylate.—J. D. Marshall's patient was a girl of ten years with articular rheumatism. Fifteen grains of the salicylate with double that quantity of sodium bicarbonate were given in chloroform water every four hours. This was continued for four days, when the child became delirious and vomited. The hallucinations were not unlike those of delirium tremens, but stopped immediately on withdrawal of the remedy. Some days later the salicylate was resumed in seven-grain doses three times daily. There was vomiting again in two days. Delirium was absent, but the urine contained blood enough to give it a deep red color. Previous to this time it had contained neither albumin nor casts. Symptoms cleared up again on discontinuance of the remedy. Hematuria from the usual doses of this salt is extremely uncommon, according to the literature on this point.

The Present Means of Combating the Sleeping Sickness.—A. Kinghorn and J. L. Todd thus summarize the general lines of prophylactic endeavor. Efforts to check the disease must be directed against the transmitting agent, the flies, either by destroying them or by preventing them from reaching and biting men. Then also we must attack the causative parasite, the trypanosome, by the treatment of persons already infected, and by isolating them so that they shall not serve as foci of infection for other individuals. Areas on which the deposition of the eggs of the fly (tsetse) is suspected should be burned over. Houses can be largely freed from flies by surrounding them with an area 300 yards on each side free from rank undergrowth or grass. Wire gauze or netting may be used for personal protection and prolonged stays in heavy vegetation near water should be avoided. The only drug for trypanosomiasis that has proven of any positive value is the preparation of arsenic known as atoxyl. The value of any drug is problematical, except after prolonged usage and careful observation of the later history of those to whom it is given. In spite of apparently successful treatment relapses are not uncommon, and a fatal result may follow just as surely as if the case had been untreated.

Causation and Treatment of Some Headaches.—W. Harris refers particularly to paroxysmal and periodic headaches and those dependent on some form of toxemia. Many periodic headaches are of the migraine form, probably referable to some temporary vasomotor disturbance. These are described in full in their varying clinical phases. Bromides are often of service during the intervals between the attacks. The actual headache is often best relieved if taken in hand sufficiently early by a full dose of butyl chloral hydrate. Nitroglycerine often brings immediate relief by reducing the blood pressure. The author next refers to periodic headaches, which may resemble true migraine somewhat closely and yet are less dependent upon an hereditary neurosis and paroxysmal vasomotor spasm than upon some peripheral cause which by its local irritant effects may set up reflexly a migrainous attack. These cases, pathologically speaking, would be strictly analogous to reflex epilepsy, such as convulsions dependent upon the peripheral irritation of worms, the irritation of a scar, etc. In many of these the removal of its peripheral cause may be followed by complete cure. The author considers the eyestrain theory as overworked and by no means entitled to all the credence it has received. Ocular headache, in which the pain is usually situated over one or both eyebrows, and is due to errors of refraction, especially astigmatism, is not uncommon. Every now and then the pain may be more periodic in some patients and may exhibit the course of symptoms familiar to us as migraine. In these cases we have to do with a reflex migraine the peripheral exciting cause of which is the visual defect and constant unequal strain upon the ciliary muscle, and these patients will probably get much relief from proper correcting glasses. Toxemic headaches arise from a multitude of causes, and their proper treatment presupposes the removal or abatement of the exciting causes. The author declares that the effect of our open air life has not received sufficient prominence in the treatment of many forms of toxemic headache. Persons who are subject to chronic headaches should cultivate the habit of keeping their windows widely open, and the hardening process thus slowly applied will not only render the individual far less susceptible to catching ordinary colds, but his tendency to frequent headaches will often completely disappear, and from a listless valetudinarian with always something wrong with him he will become brisk and healthy in mind and body.

On Opsonins and the Opsonic Index and Their Practical Value in the Treatment of Disease.—G. A. Crace-Calvert considers this question with special reference to pulmonary tuberculosis in sanatorium cases. In general the results are promising, but as yet not very decisive. The author notes that in these cases there is usually a mixed infection and that after or even while using tuberculin it may be necessary to give inoculations of a staphylococcic or pneumococcic vaccine before the patient will get well. In tuberculosis it is difficult to get a vaccine exactly corresponding to the organism causing the disease. Good effects noted are lessening of the disease activity, as shown by physical signs, and diminished sputa, improved appetite, and increased weight. In ten incipient cases the index has been below normal in four, normal or above in six. All these cases have done well regardless of their indices. In active cases with high fever the index varies from day to day. There is no apparent relation be-

tween the fluctuation of the index and that of the temperature. In the ordinary case with a fair amount of disease the index is usually about normal. In sanatorium "cures" more properly arrested cases (four old cases)—the author has found the index above normal in three and below in one, the latter having been well for six years, and possibly approximating to a normal person. The author considers this question of the index in a "cured" patient important because if it be more usually found low it seems as if the patient's resistance was not permanently affected by treatment, and that he therefore runs a risk of further infection, but before accepting this as a definite statement we want to know if the cases were truly arrested and not simply patched up temporarily, and also what their index was before they started treatment—a point that cannot be settled yet, as the method of estimating the opsonic index has not been in existence long enough to secure any results. The author considers that the opsonic theory is a most brilliant one and full of promise, but considers that its application must be greatly simplified before it can come into general use.

British Medical Journal, February 2, 1907.

The Temperature of Japanese Hot Baths.—L. Hill refers to the case of a Japanese man who could endure a bath of 114° F. for only a minute or two while totally immersed except the face. The bath was raised to this temperature from 103° in about five minutes. He came out from the bath feeling faint and asked to have the window opened. His rectal temperature had risen to 103° F. He said that his countrymen usually sit with the head and arms out of water. Under such conditions they may stand a considerably hotter temperature. They must habituate their skin to stand a high temperature, as the ordinary man habituates his tongue to hot drink. Certain hot baths at thermal springs are used particularly for syphilis. The baths range in temperature from 113° to 128° F. The intense derivation of blood to the skin induced by these baths must have a powerful effect and ought to be a most efficient way of increasing the supply of blood and its opsonin, and the activity of the phagocytes in cutaneous affections.

Repeated Abdominal Section for Perforation of Gastric Ulcers.—The patient of A. Cuff was a man of twenty-seven years who underwent two laparotomies for the perforation of two totally distinct ulcers, over four years intervening between the two attacks. In the first instance an anterior gastroenterostomy was done. Symptoms began to reappear after seven months, but over four years elapsed before a second operation was deemed necessary. His original symptoms began at the age of ten years, or thirteen years before his first laparotomy. The author declares that the onset of pain a few hours after the taking of food, when, the digestion of the meal nearing completion, the beginning relaxation of the pyloric sphincter allows the contents of the stomach to flow into the duodenum, and hence over any hyperesthetic spot in that organ is very suggestive of duodenal ulcer. An interesting fact related by the patient was that indigestible articles of food like pork pie delayed the onset of the pain, and this is in strict accordance with this theory, pork requiring four or five hours for its digestion, while mutton requires only two or three hours. This fact of the possibility of retarding the onset of the pain in cases of duodenal ulcer by the administration of indigestible food, or by eating during the digestion of a previous meal, has been noted previously. The same thing has been borne out experimentally by Cannon, who has shown in the course of his investigations on the movements of the stomach during digestion, by means of the *x*-rays, in cats, that if towards the completion of the digestion of a meal (the movement of which, owing to its admixture with a bismuth salt, was visible on the screen) a hard tablet or button made principally of bismuth was administered, its impact on the pyloric orifice immediately caused the sphincter to contract, and stopped the onward flow of chyme from the stomach to the duodenum for some little time.

Some Points on the Diagnosis and Treatment of Laryngeal Cancer.—F. Semon presents an elaborate paper on this subject. He says that if the vocal cord from which a suspected laryngeal growth springs shows at an early period of the disease a defect of mobility other than due to mechanical impaction of the growth in the glottis on phonation, this sign is almost pathognomonic for the malignant character of the tumor. The author claims that the removal, if possible, of a bit of the suspected growth for microscopical examination is perfectly justifiable, provided the patient's consent has been previously obtained, for immediate radical operation in case the verdict is in favor of malignancy. He still adheres to the opinion, frequently expressed in former publications, that in case of an early diagnosis a thyrotomy is preferable to a laryngectomy. In thirty-three cases for what seemed to be certain or very probable malignant disease of the larynx, in eight the diagnosis was shown either to have been at fault or remained doubtful. Twice the disease was tuberculous. Twice, the tumefaction seemed to be of the nature of an infective inflammation. In two the diagnosis remained doubtful between fibrosarcoma and a malignant growth. Three ceses ended fatally. Of twenty-five verified malignant cases one died and twenty-four recovered. In four recurrence took place. In extrinsic cases total laryngectomy will remain a cruel necessity until some specific shall have been discovered.

Berliner klinische Wochenschrift, January 28, 1907.

Catalytic Influence of Colloidal Metals on Hepatic Autolysis.—Ascoli and Izar report on experiments made in order to determine whether or not autolysis in the liver cells is modified by the presence of colloidal solutions of metals. They found that in the presence of such solutions the autolytic processes were very much accelerated and that this effect was produced no matter whether the fluid tested was acid or alkaline. Even very small amounts of the colloidal metals sufficed to evoke a pronounced increase in the autolytic process, and on using more of the solutions the action rapidly became more intense until a limit was reached, after which further augmentation was less effective. In order to determine whether colloidal solutions of different metals presented different properties in this respect, comparative tests were made with colloidal solutions of silver, gold, and platinum, but it was found that no easily demonstrable differences existed between the effects of the three metals named

Deutsche medizinische Wochenschrift, January 3 and 24, 1907.

Digestive Gastric Hypersecretion.—Boas says that recently this form of gastric neurosis has been found to be much commoner than has hitherto been supposed to be the case. He suggests that when its existence is suspected a dry test meal be administered in place of the customary Ewald test breakfast. For this purpose he proposes the sweet crackers ordinarily known as Albert biscuits; five of these are given, and whereas under normal conditions an hour later but little residue can be obtained from the stomach, if a hypersecretion exists, 100 to 200 c.c. of a mixture composed of a thin layer of débris and four or five times the amount of clear supernatent fluid may be expressed. Among the symptoms of the condition, which occurs most often in men, a pronounced degree of emaciation is prominent; this is probably dependent in the first place on the very notable waste of gastric juice, which may amount to two liters or more per day, and secondly, to the serious interference with starch digestion. Another troublesome symptom is obstinate constipation, and the patients also complain of disagreeable sensations about the stomach, feelings of pressure and distention, belching, and sometimes severe pain. Nausea and vomiting are rare and the appetite may or may not be impaired. While a definite conclusion regarding the nature of the affection is not yet possible, Boas is inclined to consider it as a form of nervous dyspepsia. The prognosis is not unfavorable and the therapeutic indications are especially to increase the inadequate body weight, to correct the deficiency in starch digestion, and to avoid all agencies that may give rise to an increase in the gastric secretion. This can best be effected by a diet consisting largely of albumin, fat, and sugar. Fluids need not be restricted, and in fact the use of alkaline beverages is recommended. Atropin has not been found particularly useful, but Boas recommends the administration of alkalis, particularly the citrate of sodium, of which he gives a teaspoonful four times a day.

The Mechanical Action on the Body of Lowering the Atmospheric Pressure.—Jacobi endeavors by means of a number of models to demonstrate the manner in which the circulation responds to changes in atmospheric pressure such as are observed on passing from low to high altitudes. He concludes that there is a considerable dilatation of the pulmonary vessels, the veins, and the capillaries, so that blood is more or less stored in these districts. In consequence of this the patient is, as it were, bled into his own vessels and the blood-forming organs respond by producing an increased number of red corpuscles, and in this way the author endeavors to account for the increased number of erythrocytes and the high hemoglobin percentage observed as a result of sojourn at high altitudes.

Book Reviews.

TRANSACTIONS OF THE ASSOCIATION OF AMERICAN PHYSICIANS. Twenty-first Session, held at Washington, D. C., May 15 and 16, 1906. Volume XXI. Philadelphia: Printed for the Association, 1906.

IT is hardly necessary to attempt to point out the great interest and value of the series of papers that are here presented in collected form. So many contributions of importance are included among the fifty odd that were read before the last meeting of the Association of American Physicians, that it is difficult to make any selections for especial mention; but attention may be directed to the discussions of the subjects of blood pressure, pentosuria, the serum treatment of exophthalmic goiter, various blood diseases, and arteriosclerosis. The volume comprises a record of contemporaneous medical work of much significance, and embodies the opinions of many of the best known physicians in the country on problems of the deepest import.

KOSMETISCHE HAUTLEIDEN. Von Dr. S. JESSNER, Konigsberg i. Pr. Würzburg: A. Stubers Verlag (Curt Kabitzsch), 1907.

UNDER this title Jessner describes the treatment of such affections of the skin and its appendages as may be considered more particularly from the cosmetic standpoint. Accordingly, the little volume of 124 pages is distinctly practical in its subject matter, and may safely be recommended to all readers of German as an attractively written treatise on a subject on which the author is well qualified to speak with authority.

DES HAARSCHWUNDS URSACHEN UND BEHANDLUNG. Von Dr. S. JESSNER. Konigsberg i. Pr. Fünfte Auflage. Würzburg: A. Stubers Verlag (Curt Kabitzsch), 1907.

THIS is a brochure of fifty odd pages, containing the views of the well-known author on the causes and treatment of alopecia. Seven varieties of the affection are dwelt upon, and numerous prescriptions for local applications are given.

OBSTETRICS FOR NURSES. By JOSEPH B. DELEE, A.M., M.D., Professor of Obstetrics, Northwestern University Medical School, etc., Chicago. Second Edition, Revised and Illustrated. Philadelphia and London: W. B. Saunders and Company, 1906.

ALTHOUGH published but a comparatively short time, Prof. DeLee's book has won considerable favor. It conveys an excellent idea of the subject to the nurse, and may also be regarded as a helpful book to medical students about to undertake their practical work in midwifery; for, as the writer states in his preface, many of the duties of the nurse devolve upon the latter in their early years of practise. The book is divided in the usual manner into several parts, in which are considered the anatomy and physiology of the whole reproductive cycle, the conduct of pregnancy, labor, and the puerperium, and the pathology of pregnancy. There is no one part which can be picked out for particular comment; the subject is presented in clear, concise manner, and well illustrated by photographs which are of uniform excellence. The introduction constitutes an important part of the work, for it calls attention to the importance and value of proper obstetric nursing, a fact which it is difficult to get nurses in training to appreciate.

TEXT-BOOK OF COMPARATIVE GENERAL PATHOLOGY, for Practitioners and Students of Veterinary Medicine. By Prof. Dr. TH. KITT of Munich. Authorized Translation by Dr. W. C. CADBURY, Assistant Demonstrator of Pathology in the University of Pennsylvania. Edited with Notes and Additional Illustrations by Dr. A. J. SMITH, Professor of Pathology in the University of Pennsylvania. Chicago: W. T. Keener and Company, 1906.

THE need of a book such as the one here translated is evident, for the impressions gained from a work on pathology, which is framed primarily on the conditions found in the human body, are necessarily inaccurate and incomplete. The fundamental processes of disease are the same, no matter in what type of animal they occur, but the variations of the same type of lesions in different species may be sufficiently marked as to make a description based upon the changes met in any given animal confusing and inadequate. An extract from the preface will best explain another feature of the book. The latter reflects the tendency of modern pathological teaching to direct the thoughts of the reader along lines of pathological physiology, to make the student reason for himself from given anatomical data and appearances as to the necessary functional faults and failures. A book of this kind also possesses worth for the student of human medicine, for comparative pathology bears an intimate relation to the latter, and there is great need that experimentalists should be in the best possible position to appreciate the reactions peculiar to these experimental animals. The translation is good, though literal, but the illustrations are hardly on a par with those met with in most American text-books.

DIE TUBERKULOSE DER MENSCHLICHEN GELENKE SOWIE DER BRUSTWAND UND DES SCHADELS. Nach eigenen Beobachtungen und Wissenschaftlichen Untersuchungen. Von Prof. Dr. FRANZ KÖNIG, Berlin. Mit 90 Textfiguren. Berlin: Aug. Hirschwald, 1906.

THIS book is dedicated to v. Bergmann on the occasion of his 70th birthday by one of the foremost German specialists in bone diseases. It is divided into two parts, the first of which is concerned with a description of the pathological anatomy of joint tuberculosis, the knee joint being used as a basis for the presentation of the subject. The various forms of tuberculous arthritis and their clinical course are related in detail, and in conclusion the treatment is discussed, the author inclining to the idea that this must be mainly operative. He is not inclined to look with favor on the mode of treatment developed by Bier, and has frequently observed the formation of abscesses in such cases, and has also been compelled to resect joints which were treated in this manner by others.

In the special part of the book he takes up the discussion of tuberculous disease in the joints of the leg, the arm, the thorax, and the skull, in its pathological, clinical, and therapeutic aspects, and presents numerous statistical studies from his extensive clinical material. Although the book includes less than two hundred pages, it contains a wealth of material which will serve as an excellent manual for the student and a work of reference to the practitioner. For the latter it is of particular value as a means of aiding diagnosis and presenting the indications for operation. The radical treatment is usually favored at the expense of the conservative, but, considering the excellent results which have been attained by many with the latter, the writer's contention will probably not find acceptance by any means universal.

EXPERIMENTAL PSYCHOLOGY. A Manual of Laboratory Practice. By EDWARD BRADFORD TITCHENER. Volume II. Quantitative Experiments; Part II. Instructor's Manual. New York: The Macmillan Company, 1905.

THIS volume consists of a lengthy introduction on the rise and progress of quantitative psychology, and chapters on preliminary experiments, on the metric methods, on the reaction experiment, on the psychology of time, and on the range of quantitative psychology. As indicated in the title, it is a laboratory manual, and is intended for those engaged in teaching the subject.

THE TREATMENT OF DISEASES OF THE DIGESTIVE SYSTEM. By ROBERT SAUNDBY, M.D., M.Sc., LL.D., F.R.C.P., Professor of Medicine in the University of Birmingham; Senior Physician to the General Hospital; Consulting Physician to the Eye Hospital and to the West Bromwich Hospital. Philadelphia: J. B. Lippincott Company, 1906.

THIS book of 120 pages is based on the author's personal experience in treating diseases of the digestive tract. While the volume deals with the subjects under discussion in a pleasant and satisfactory manner, it contains little or nothing that cannot be found in any book on either Practice or Therapeutics.

THE DISEASES OF WOMEN. A Handbook for Students and Practitioners. By J. BLAND SUTTON, F.R.C.S. Eng., Surgeon to the Middlesex Hospital, and Senior Surgeon to the Chelsea Hospital for Women, and ARTHUR E. GILES, M.D., B.Sc. Lond., F.R.C.S. Edin., Surgeon to the Chelsea Hospital for Women, and Gynecologist to the Tottenham Hospital. Fifth Edition, with 129 Illustrations. London and New York: Rebman Company, 1906.

THE new editions of this well-known text-book appear with regularity and rapidity. The present volume is but little larger than its immediate predecessor; the new matter introduced deals with chorionepithelioma, extrauterine pregnancy, and tumors of the ovary, including an entirely new section on metastatic cancer of that organ. The authors have been unusually successful in their endeavor to compress all the established facts of gynecology within the compass of one volume of moderate size, and they have fully justified the statement made in the preface, viz., "We still believe that when surgical authors are able to restrain their vanity, and refrain from publishing notes of successful cases in text-books, the established facts of the art can be presented in a very convenient compass." Nothing of importance is omitted; there are numerous illustrations, all of a high order of merit, and the paper and press work are excellent. The arrangement of the subject matter differs from that adopted in most books, and the operative procedures are placed together, occupying the last eight chapters of the book. All of these features are to be commended, and as a handbook for the student or practitioner this volume will be particularly acceptable.

Society Reports.

THE PRACTITIONERS' SOCIETY OF NEW YORK.

206th Regular Meeting, Held December 7, 1906.

THE PRESIDENT, DR. T. MITCHELL PRUDDEN, IN THE CHAIR.

DR. W. GILMAN THOMPSON presented a case of muscular atrophy involving the muscles of the arms and shoulders, with marked tremor, but no sensory disturbances.

Dr. M. ALLEN STARR regarded the case as one of amyotrophic lateral sclerosis. He stated that in this disease the progress of the atrophy and paralysis was more rapid than in progressive muscular atrophy, and there was more constant and violent fibrillary twitching of the muscles. The entire arm was affected simultaneously, whereas in progressive muscular atrophy the atrophy ascended the arm and there was exaggeration of the knee jerks, indicating an affection of the lateral columns of the cord, as well as the affection of the anterior horn.

Dr. CHARLES L. DANA thought the case was one of amyotrophy of the Aran-Duchenne type.

A Case of Epithelioma of the Eyelid Treated with Radium.—Presented by Dr. ROBERT ABBE. The patient was a man forty-three years old, with an epithelial carcinoma of the lower eyelid extending from the inner canthus to nearly the outer canthus, only a quarter inch of mucous membrane remaining free. It measured one and one-eighth inches in length, and presented a solid growth a half inch in thickness and the same in depth, and involved the entire structure of the lid. Dr. Abbe showed colored plaster casts of the growth as it was before radium treatment was begun in June, 1906, and stated that a microscopic examination had revealed true carcinoma. Five applications of the strongest radium tube were made, of one hour each, and in two weeks improvement began. Progressive retrogression had followed, until now a small remnant only remained at the inner end. To this, after a five-months' interval, half-hour applications of radium had again been made, which it was hoped would be enough to complete the cure. Dr. Abbe said he had had six cases of epithelioma of the eyelid, all either cured or being cured, and it seemed to him to be a specific to be entirely relied upon in this type of disease. He also showed casts of the case of sarcoma of the eyelid exhibited at a meeting of the Society two years ago, which had remained entirely healed.

Neuralgia and Neuritis of the Arms and Legs.—By Dr. CHARLES L. DANA. (See page 297.)

Dr. EDWARD G. JANEWAY drew attention to the two types of what was considered lumbago. One was situated in the muscles of the back; the other was dependent upon disturbance of the lumbosacral joint. This was apt to be produced by standing bent forward for some time, especially in a cold place. Physicians, as a rule, took this for ordinary lumbago. It was apt to occur in those with gouty or rheumatic tendencies. The speaker said that in his experience the neuralgia of persons with angina pectoris was more apt to involve the nerves distributed to the little or ring finger than appeared to have been the experience of Dr. Dana. He alluded also to a case where there was intense pain in the right arm of a patient who died a week later, and in whom calcification and thrombosis of the right coronary artery and rupture of the interventricular septum was found.

Dr. BEVERLEY ROBINSON said he had found a special massage roller very useful in a case somewhat similar to those of cervical neuralgia described by Dr. Dana. The roller consisted essentially of a series of wooden balls about one inch in diameter, strung along a properly covered iron wire. At either end of the roller were handles similar to those of a pulley apparatus used by athletes. For cases of brachial neuritis, as well as for cases of this disease located elsewhere, he had found a compound of menthol, salicylate of methyl, and lanolin at times beneficial. This was rubbed gently into the skin and covered with a layer of absorbent cotton and a light gauze bandage. The first effect of the application was cooling, but in a few moments an agreeable and marked warmth followed locally. The ointment must not be used over an abraded surface, or it would occasion severe irritation.

Dr. V. P. GIBNEY said that one of the causes of neuralgia of the spine, especially the lower portion, was a displacement or a sprain of the sacroiliac joint. He had found the small tip of the Paquelin cautery a most efficient remedy in brachial neuralgia, and, contrary to expectation, the use of the cautery—small touches, not strokes—did not leave any scars. Numerous points touched faded out into a rich brown color, and gave to the shoulder, arm, or forearm the appearance of one exposed to the sun. For the neuralgia induced by piano playing, the treatment had, in his hands, been productive of most gratifying results.

Dr. ABBE said he would speak only of the phase of brachial plexus neuralgia referred to by Dr. Dana as sometimes hysterical. Ten years ago he reported some cases in which he had operated six and eight years previously for intractable neuralgia of the arm where previous stretching of the nerves followed by resection and finally amputation, had failed to relieve. He had then made an intradural resection of the posterior roots of the brachial plexus as they emerged from the cord (*Boston Medical and Surgical Journal*, October 1, 1896). Temporary relief seemed to be afforded, but these patients were still living, and had, to a moderate degree, the same evidences of pain. In all there had been a consensus of opinion that there was a considerable hysterical element that masked the value of pain as a symptom of disease or an index of the utility of operating by this method. Nevertheless, Dr. Abbe said, he would not hesitate to resort to this novel and beautiful method with some hope in a suitably defined case.

A Case of Ophthalmoplegic Migraine of Intermittent, Recurrent Type of Hereditary Origin.—Dr. M. ALLEN STARR reported this case. The patient was a young man whose mother had suffered from migraine and who had been subject to attacks of sick headache since the age of twelve. In connection with each attack of migraine for the past five or six years, the patient had a total third nerve paralysis on the left side lasting about five or six days, and disappearing either as the headache passed off, or perhaps lasting a few days longer than the headache. When he was first seen he had a typical third nerve paralysis, ptosis, immobility of the eyeball, with external strabismus and dilatation of the pupil. At the end of a week this condition had entirely passed off. Such an intermittent paralysis of the third nerve, Dr. Starr said, had been described by various writers, but it was a very rare condition, and was probably, in a majority of cases, due to an attack of migraine.

Dr. CHARLES STEDMAN BULL said he had seen two cases of ophthalmoplegic migraine, one in a man and the other in a woman. In both the left eye was affected. In both the attacks were irregular in their appearance, varying in frequency from three weeks to two months, and in duration from four days to one week. In every attack the first symptom was severe pain in the supraorbital and nasal branches, followed by sudden paralysis of all the branches of the third nerve, including those to the sphincter iridis and ciliary muscle. The secondary divergent squint was marked, and there was some puffiness of the upper lid. All treatment proved futile in both cases, though the neuralgia could be controlled by hypodermic injections of morphine. The attacks ceased as suddenly as they began, the pain first yielding, and then the ptosis began to disappear, the last symptom to disappear being the mydriasis.

Three Cases of Ureteral Calculus Detected by X-Ray and Successfully Removed by Operation.—Dr. ABBE showed three large calculi removed from the ureters of patients during the past year, after perfect Roentgen radiographs had located the position of each, which was exactly

opposite the third lumbar transverse process. The history of pain in each varied from two to eight years, and left no question but that they had been in the ureter during that time. A channel had been furrowed down the side of the two larger ones, explaining the absence of hydronephrosis. In one case there had been but one attack of hematuria, in another none, and in the third not even the centrifuge deposit of several urine specimens showed blood on the microscopic slides. This, the speaker said, was a surprise to him, as he had rather learned to look upon the detection of blood corpuscles in centrifuge specimens after pain as almost inevitable. Dr. Abbe said the method of operation in these cases was worthy of record. In each he had used his method of muscle separation, without cutting, with perfect satisfaction. This gave a strong scar, with no chance of hernia. After separating the three muscle layers, the finger quickly raised the peritoneum from the psoas muscle, and, the perureteral fat being exposed by tearing through its cellular sheath, the finger instantly detected the calculus in the ureter. It was removed through a longitudinal cut, which was sewn up by fine catgut. Another long piece of fine catgut was then caught into the psoas muscle, near the repaired ureter, and both ends passed up through a small rubber tube which was run down to the muscle, and there held by tying the outer ends over a pin transfixing the outer end of the tube. This was to be kept *in situ* to anticipate any need of drainage for two days, and the outer wound closed layer by layer around it. On the second day the tube was withdrawn, and on the following the catgut also. The patients all made a quick and perfect recovery.

Dr. Edward G. Janeway said that his experience did not warrant the certainty Dr. Abbe had in the radiograph. He had in mind the case of a priest who came to him from Pennsylvania with the clinical evidence of renal calculus, and that diagnosis was apparently correct. The patient then consulted surgeons, who had radiographs taken several times with negative results. In consequence of this, one surgeon, after a week's observation in the hospital, declined to operate. Another surgeon later operated, notwithstanding the failure of the *x*-ray diagnosis, and removed a large calculus.

Dr. George L. Peabody asked whether the attempt to get an *x*-ray photograph of a calculus was not sometimes unsuccessful, and expressed the opinion that in his own experience it had failed to aid in the diagnosis in a kidney in which surgery had subsequently demonstrated its presence.

Dr. Beverley Robinson said he noticed that in one of Dr. Abbe's cases there was no hematuria; in another, hematuria was noticed for the first time only three weeks before operation. These facts were interesting, because we were accustomed to regard hematuria as usually present when a stone existed in either the ureter or the kidney. Too much importance should not be attributed to *x*-ray findings in the matter of ureteral stone. Sometimes a shadow was found, and operation failed to reveal a stone; again, there was no shadow in the picture, and subsequently an operation might prove the presence of stone.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON PEDIATRICS.

Stated Meeting, Held January 10, 1907.

Dr. Godfrey R. Pisek in the Chair.

Case of Diabetes Insipidus.—Dr. Eli Long presented a boy, eleven years old, a son of a tuberculous parent, whose disease began with or followed an attack of measles eight years ago. He drank large amounts of water during the day and a couple of quarts during the night. He would not eat his breakfast without drinking two or more glasses of water. If water was refused him he would climb up and put his mouth under the faucet. His twenty-four hours' urine measured fourteen pints, or seven quarts, and often it was eight or nine quarts. The amount of urine excreted amounted to one-third his body weight. The specific gravity of the urine was from 1001 to 1002, and there was no sugar. There was some edema of the optic nerve on one side and a choroiditis on the other, probably syphilitic in origin. The mother had one miscarriage following his birth, and the father died of tuberculosis. The cough, bloody sputum, glandular enlargement all pointed to syphilis, or tuberculosis, or to both.

Case of Diabetes Mellitus.—Dr. Eli Long presented a girl, ten years old, who had a polyuria resulting from a fall. Three weeks ago, while skating, she fell and struck the back of her head. She since had lost much flesh, had wet the bed—a thing she had not done in five or six years. Her thirst had greatly increased, and she passed large amounts of urine daily. An ordinary chamber was filled during the night only. The specimen contained so much glucose that the chemist thought that there had been some error made, and asked for another specimen. A further and complete report would be made later.

Dr. Schwarz said that he had a case of a boy of twelve years under observation, who presented features of interest. The father died of cerebral hemorrhage, and he had always been very nervous. The mother had always been well. The child was exclusively breast-fed up to fifteen months of age. Even at this time the mother noticed that he would crave water; after taking two or three ounces of water he would then take the breast. There was a great deal of polyuria. When the child was three years old, the mother had to go out working, but could get no one to care for the boy, because he drank so much and wet the floors. He had a light attack of scarlet fever when five years old, and an attack of measles when seven years old. His general health had been good. His sight was good and he excelled at sports. The boy was first seen in August, 1905, when he weighed 66 pounds. He then passed 10,400 c.c. of urine in 24 hours. He passed 39 ounces at a time, and 344 ounces in 24 hours. On March 3 he passed 11,800 c.c. On a salt-free diet he passed 8,000 c.c. The urine had a specific gravity of 1,0025, and there was no albumin or casts, and the urea amounted to 310 grams in 24 hours. Hemoglobin was 85 per cent., red cells 4,800,000, and white cells 8,000. The question would arise in this case whether there was present simply a polyuria, or a polydipsia, or whether the condition was due to cerebral syphilis, trauma, or heredity.

Dr. Henry Koplik called attention to two cases he had seen with supposed diabetes insipidus; both ended up with cerebral growths.

Dr. Sara Welt-Kakels reported two cases of interest. One was a little girl, nine years old, who fell, and she believed her diabetes insipidus to be due to this injury. She passed from four to five quarts of urine daily. After having been under treatment for ten months, with great improvement, she one day came to the dispensary, and she could not open her eyes. Every branch of the motor oculi were paralyzed, and she had been taken ill with some meningeal trouble. The other case was a boy, six years old, who weighed thirty-six pounds, and who passed water in large amounts, the smallest quantity passed in twenty-four hours being 8,000 c.c. Both these children took so much fluid that there was little opportunity for taking nutritious food.

Dr. H. W. Berg said that many of these cases of so-called diabetes insipidus were due to causes other than cerebral or disease of the renal parenchyma. In one case that was supposed to be typical, the removal of a vesical calculus cured the condition. In another case the removal of an enlarged prostate cured the polyuria. Many of these cases of diabetes insipidus were due to peripheral irritation, and the general practitioner should be cautioned against looking upon it as an entity.

Two Cases of Visceral Syphilis in Children.—Dr. SARA WELT-KAKELS presented these cases.

The first case was presented to the Section two years ago. (See MEDICAL RECORD, Vol. LXVII., page 355). At present the hemoglobin (Dare's hemoglobinometer) was 64 per cent., red cells 4,460,000, and white cells, 13,200. The differential count showed the polynuclears 61 per cent., small lymphocytes 28 per cent., large lymphocytes 10 per cent., eosinophiles 1 per cent. The color index was 0.71. The child had been placed on intramuscular injections and had made considerable improvement.

The second case was that of a boy over three years old, whose parents were healthy, and with no luetic history. The present illness began five months ago, when he lost his appetite, had some fever, cough, and profuse perspiration, disturbances of digestion, profuse diarrhea, was losing flesh, etc. When first examined the child was very cachectic, moaning and crying when touched, especially when the abdomen was palpated. The skin and mucosæ were pale. The superficial lymphatics were somewhat enlarged. The rectal temperature was from 101° to 103°. The abdomen was moderately protuberant and the superficial veins markedly distended. There was no ascites. The liver occupied the greater part of the abdominal space, its surface was hard and uneven, with rounded and thickened border. The left lobe did not participate in the great increase in size of the liver. The surface of the spleen was even and hard, and the lower border projected about two fingers below the free border of the ribs. There was diarrhea, and the stools contained fibers of meat and undigested vegetable matter. The red cells numbered 3,580,000, the white cells 26,600, hemoglobin 46 per cent., color index 0.69. The differential count showed polynuclears to be 51.5 per cent., large mononuclears 37.5 per cent., the small mononuclears 2 per cent., eosinophiles 3 per cent., and no mast cells. Intramuscular injections of mercury produced the most marked improvement, so much so that the mother regarded the child as a healthy one. Intramuscular injections of bichloride of mercury were given three times a week.

A Case of Apyretic Pneumonia.—Dr. A. L. GOODMAN reported this case. The patient was a girl eight years old, who, while attending to her regular school duties, was troubled with a short dry cough of a very persistent character. The mother took the temperature, and found it normal. On the third day from the commencement of the cough, Dr. Goodman saw the patient. The temperature during the three days varied from 99.2° to 99.7° F., and the mother's thermometer corresponded with his. The patient had a frequent, short, dry, cough. The throat examination was negative. The respirations were 24, and painless. The left side of the chest on percussion was normal, and the breathing sounds were somewhat exaggerated. The right side of the chest, almost from the base to the apex, was dull; the breathing sounds were distinctly bronchial in character, with very few friction sounds. The vocal fremitus was markedly increased. There was no pain, the child's only discomfort being the persistent cough, which disturbed her rest day and night. The temperature and respirations were noted every three hours. The respirations varied between 24 and 28. The pulse rate ranged from 88 to 100. The treatment consisted in mild stimulation and rest, plenty of air, and the usual other hygienic and dietetic procedures adopted in acute lobar pneumonia. The physical signs diminished day by day, and on the eighth day the temperature registered 98.6°, and after that remained normal. On the twelfth day all the physical signs of consolidation were gone and the cough also disappeared. There was no history of syphilis or tuberculosis in the family.

Enlargement of the Epitrochlear Glands in Infants.—Dr. ALFRED F. HESS read this paper. He said that the data of which he made use were gathered in the course of examination of dispensary patients of two years of age and under, who were treated for various ailments, chiefly for errors in diet. They numbered 225. He was surprised to find how few babies had no superficial glandular enlargements, there being found but six among the 225 cases; of these, four were well nourished and two poorly so. Considering certain facts, it seemed to him that they should not continue to attribute all these lymphatic enlargements to minute lesions of the skin, for instance of the scalp, but must regard them as frequently physiological to infancy. Among the 197 cases in which posterior cervical glands were searched for, they were found 173 times. These enlargements he believed to be due to lesions of the scalp or pharynx, to be partly of congenital origin, and to a small degree to systemic infection. The glands next in order were the inguinal, and they were enlarged in 119 cases out of 147 examined. Circumcision appeared to play no part. In infants, as well as in older children, the submaxillary and anterior cervical were frequently palpable. Enlargement of the axillary gland was of a common occurrence. Of all the superficial glands, enlargements of the epitrochlear was the most exceptional. Besides the 225 cases referred to, he also examined 75 more for the presence of epitrochlear glands. Of these 300 cases numerous infants were found to have one enlarged epitrochlear gland, but no importance was attached to this unless this was large. Minute bilateral glands were found to be very common, and were found in twenty-six cases. Large bilateral glands were found, however, in only fifteen of the 300, and six of these patients had syphilis, two of them being only seven weeks old. One had an enlargement to the size of a marble. Of the remaining nine cases, three were probably syphilitic; one had a large liver and spleen, and the mother gave a history of two miscarriages; the mother of the second had had three miscarriages, and eight children died in infancy; the third child had snuffles since birth. Of the six remaining cases with large epitrochlear glands, two had tuberculosis with general glandular involvement, and one had furunculosis of long duration. He was unable to state the cause of the enlargement in the other three cases. Possibly syphilis might play a rôle in these also. However, the fact that bilateral enlargement occurred so rarely in infants, and proved of syphilitic origin in the majority of cases was certainly a striking fact. These figures could not be applied to older children. Since he had paid particular attention to the epitrochlear glands he had been given an opportunity of examining fifteen cases of hereditary syphilis in infants. Seven of these had large bilateral epitrochlear glands, in four they were small, in three they were not palpable. Dr. Hess wished especially to emphasize the fact that all symptoms of syphilis might disappear under the mercurial treatment, but the epitrochlear glands might persist as the sole objective symptom of the disease. Therefore, in some cases only a routine examination for these glands would reveal, or even suggest a previous infection. The presence of an enlarged spleen, associated with large bilateral epitrochlear glands, occurring in an infant, was good evidence of syphilis. In summing up his estimation of the value of epitrochlear glandular enlargement, he stated that its importance was not as an early sign of hereditary syphilis, that its absence by no means cast doubt upon the diagnosis, but that its presence might serve for a long period as the sole landmark of previous infection.

A Clinical Study of Congenital Syphilis.—Dr. W. B. JENNINGS read this paper. He said that when one considered the annual infant mortality of New York City in children, one year old or under, was more than 16,500, and out of that number only 78 reported deaths from specific disease, one would naturally conclude that the latter disease was not a common one or particularly fatal. But his experience taught that this was not so. During the year 1905 there were reported to the Health Department 169 abortions, 3,903 "congenital debility," premature birth, preternatural births, together with malformations and marasmus under three months of age, and 6,352 still-births. Considering these cases, he thought it was reasonable to suppose that in a large per cent. death was due to specific disease. Dr. Jennings had a series of 65 cases of specific disease,

all under one year of age, all seen from time to time during the past three years. There were 33 males and 32 females. A positive family history of syphilis was obtained in 25 cases, the greater number giving a paternal infection. From a table given, it was shown that the greatest number of cases in this series were only one month old or under, the second and third months of age being the next most frequent. This corresponded to the observations of Miller of Moscow, and Holt of this country. As a rule, if pemphigus was not present at birth, it would appear within forty-eight hours, if it appeared at all. Pemphigus appeared in 5 per cent. of his cases, and all had bullæ on body and head, as well as the hands and feet. Snuffles was one of the most common symptoms, and persisted for a long time. The skin eruptions might be described as syphilitic dermatitis, not unlike erythema intertrigo, except that there was a marked desquamation. It was most commonly seen around the genitals and buttocks, and inner sides of the thighs; it often extended over the abdomen, as well as the extremities. Macules, papules, superficial ulcers, and condylomata were the forms of eruption most frequently met with. Ulcers and fissures of the lower lip and mucous patches in the mouth were also present. The hair was affected in but a few cases. One case had an apparent paralysis of the soft palate, together with a laryngitis. In only one case was any joint affected. One or two cases of dactylitis were seen. Fully 40 per cent. of the cases were well nourished. In children over six months old there was often a delayed dentition. Marasmus was present in about 6 per cent. of the cases. Rachitis was present in two or three cases, and in one case, a child of nine years, a diagnosis of gumma of the liver was made. The glands enlarged were, in order of frequency, the inguinal, cervical, axillary, and epithrochlear. Porrot's nodes were not observed in one case. The prognosis was unfavorable if the child was without treatment; they all responded rapidly to treatment, mercurial inunctions. Gray powder given internally was of value; if it caused diarrhea Dover's powder was added. The black wash was used for the snuffles.

Dr. Henry Koplik emphasized the importance of not placing much value on enlargement of the lymph nodes, unless accompanied by certain symptoms. If one met with an extensive eruption apparently syphilitic, enlargement of the lymph nodes was quite significant. Dr. Koplik said he would not make a diagnosis of syphilis merely on the enlargement of the epitrochlears. After years of study he believed that *per se* enlargement of the lymph nodes was of little diagnostic value when unaccompanied by other clinical symptoms.

Dr. H. W. Berg said that Dr. Fessenden Otis, as far back as 1881, would never allow a clinic to pass in which he showed syphilitic patients without calling attention to the fact that the epitrochlear glands were enlarged in syphilis, and he ascribed so much importance to such enlargements in the diagnosis of syphilis that he went to the other extreme and considered such enlargements as almost pathognomonic of syphilis, in which, of course, he was wrong. Enlargement of the epitrochlears meant the suspicion of syphilis.

Dr. A. Rose said that in December, 1900, Hochsinger described an affection which he named hereditary syphilitic phalangitis, the first ever given. Within twenty-five years he had collected fifty-five cases. The reason there were so few on record was, first, omission of exact examination, and, secondly, difficulty of recognizing the symptoms in some instances. This phalangitis was more frequently found on the fingers than the toes. Hochsinger preferred the name phalangitis to that of dactylitis because the disease was exclusively an osteitis. It was a typical and characteristic manifestation of hereditary syphilis, and began at the proximal phalanges. Hochsinger found, by means of the Roentgen rays that the osteitis began at the borders of the bone and cartilage, not only in the phalanges, but in the metatarsal or metacarpal bones when they were simultaneously affected in phalangitis hereditosyphilitica. The characteristics were: the predominance of the affection of the proximal phalanges, the absence of suppuration or perforation outward, inclination to spontaneous restitution and the subacute course of the disease, the absence of pain during its development. The proximal end of the proximal phalanx where the osteitis began became enlarged, giving the finger a bottle-shaped appearance, the fingers becoming broader and longer. The soft parts did not participate, only the skin being stretched became thinner, was shiny and rose colored. The affection was multiple, but not symmetric. The joints remained intact. Hereditary syphilis affecting the fingers after the first year of life, as a rule, did not show the same characteristics; here caries might set in, as also arthritis and participation of the soft parts. Hereditary syphilitic phalangitis in infants was one of the best accessible forms of hereditary syphilis to therapy. Local treatment was not required. General antisyphilitic means would accomplish complete and permanent cure within six to ten weeks.

Dr. Schwarz said that what Dr. Jennings had stated regarding pemphigus was equally true of pemphigus neonatorum, and in this latter form the fluid removed from the blisters would show eosinophile cells which were not present in the other form.

Dr. Sidney V. Haas said that after investigating the importance of enlargement of lymph nodes in babies at the Vanderbilt Clinic, he had given up in despair, finding them to be the regular thing, and of no particular diagnostic value.

Dr. Henry W. Hale, Jr., said that the treatment depended somewhat on the time of the infection. The more recent the infection, the more severe were the cases, and they required intramuscular injections, not responding so well under the ordinary methods.

Dr. Henry Heiman recalled some cases where the ordinary method of treatment failed, and which required intramuscular injections. The more recent the infection, the more severe the symptoms, and the more energetic treatment was then required.

Dr. Charles N. Dowd said that the cases he saw were late ones, and in the older children the bone lesions predominated, particularly those of the tibia. Joint lesions were occasionally seen. Dr. Dowd said he had been looking for years for a case of enlarged cervical glands due to syphilis, so large as to require surgical interference. He had failed to find but one case.

Dr. Henry W. Frauenthal said that these glands might have been syphilitic, but that it was the tubercular infection which caused their breakdown.

Dr. Dowd thought that Dr. Frauenthal was correct, and he was not sure that the case he referred to was not one of tuberculous lymph nodes in a syphilitic child.

Dr. B. Lapowski said that in 90 per cent. of the cases injecting the liver of a syphilitic into an ape would inoculate that ape. When certain spirochetes were found the diagnosis was positive. He never relied upon intramuscular injections of mercury in the treatment of syphilis; he never failed if treatment was carried out by inunctions properly given.

Dr. Hess, closing the discussion, said that enlargement of the epitrochlears, to be of any value, should be bilateral. Again they should not be too small. The cases Dr. Otis showed in 1881 were cases of acquired syphilis, and not congenital, to which his paper referred.

Dr. Jennings closed the discussion.

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting, Held January 24, 1907.

Dr. Howard C. Taylor in the Chair.

An Unusual Specimen of Tubal Gestation. Dr. H. Grad presented this specimen, which showed very nicely the amnion and chorion. Ectopic gestation was not diagnosed at the time. She was seen two weeks after a sup-

posed abortion, and a retroverted uterus was found. When the patient was placed under ether, lifting the uterus into position revealed this mass in the pelvis. The abdomen was opened and the unruptured ovum was found in the pelvis and among blood clots.

Specimen of Cyst of the Vagina.—Dr. H. GRAD presented this rare specimen. He had not time to determine just what variety of cyst it was. He would attend to this and report on it later. In all probability the cyst was due to occlusion of the duct of one of the vaginal glands.

Vaginal Hysterectomy for Septic Peritonitis Following an Artificial Abortion.—Dr. ABRAM BROTHERS reported the case of a woman, aged 33, the mother of two children, who skipped her usual menstrual period by two weeks. She visited a midwife, who introduced a catheter into the uterus. This was associated with much pain, and was followed by uterine bleeding and fever. The family physician was called, and she was found to have a temperature of 104° F., and he at once proceeded to curette her and wash out the uterine cavity. This was followed by a drop in the temperature to 101°, with a pulse of 90. Dr. Brothers saw her at this time, and found an area of local peritonitis behind the uterus, for which he ordered rest, ice, and opiates. The prognosis seemed to be favorable. After the lapse of 36 hours he was called in great haste at night to meet the family physician, who was greatly alarmed at her condition. In spite of large and continued doses of opium and the constant supervision of a trained nurse, the peritonitis rapidly spread and the woman was evidently suffering intense pain, which kept her continually moaning and shrieking. The temperature and pulse became markedly increased and the abdomen greatly distended, and was the seat of exquisite tenderness. The woman was hurried to the Beth Israel Hospital and was operated on at 2 o'clock in the morning. On opening the posterior cul-de-sac a little accumulation of pus escaped. Under the impression that the uterus had been perforated by the catheter, which was under the circumstances in an infected condition, he did a rapid vaginal hysterectomy with clamps, draining the peritoneal cavity with gauze. The temperature at once dropped and the patient went on to complete recovery. No perforation of the uterus was discovered.

Laparotomy for Infected Ectopic Gestation.—Dr. ABRAM BROTHERS reported the case of a woman who gave the history of irregular bleedings, cramps, and sensations of faintness. A local examination revealed an enlarged uterus, but apparently nothing more. A curettage without anesthesia was ordered and performed by the house surgeon, who neglected to have the scrapings examined. Several days later she complained of slight pain in the right iliac region, and the chart showed a low grade of temperature. Examination revealed a small mass in the right pelvis, which was diagnosed as a parametritis. Nothing was felt in Douglas' cul-de-sac. At the end of two weeks, in spite of ice and rest, the mass increased in proportions rather rapidly, and, suspecting a purulent process, operation was advised. She was anxious to go home, as her general condition was not bad. The presence of a low grade of temperature, with accelerated pulse, induced them to insist on her remaining, and finally, three weeks after the curettage, she was induced to submit to operation. Laparotomy with exsection of the umbilicus was done. No free blood was present in the peritoneal cavity. The right-sided mass was glued to the omentum and anterior abdominal wall. During the manipulation to isolate the tumor there was a sudden gush of pus of chocolate color. The tumor was shelled out of its adhesions and removed. Within the peritoneal cavity it seemed to have the diameter of an ordinary sized baseball. The abdomen was closed to the lower end of the incision, where a small drain was left. Recovery was uneventful. On splitting open the tumor a small amniotic sac was opened, and within it a tiny embryo was discovered.

Dr. HOWARD C. TAYLOR recalled a case similar to the one reported by Dr. Grad, in which he curetted for a supposed miscarriage. After three weeks he opened the abdomen and the fetus was found. The woman had been bleeding slowly and lost much blood, and was very anæmic, but at no time did she develop an hematocele.

Dr. HERMAN J. BOLDT confessed that ten years ago he knew more about the diagnosis of ectopic gestation than he knew to-day. It had occurred to him many times that a patient presented herself with the typical symptoms of ectopic pregnancy, and he would open the abdomen only to find a suppurating tumor. Especially in pus cases was one liable to trip up on in diagnosis. He recalled one case that Dr. Brothers had seen, and which he subsequently saw two or three times, with the impression that the slight atypical bleeding that was present was caused by a postpuerperal endometritis following an abortion. One morning he was called, and made a diagnosis of ectopic, and the patient was subsequently operated on for ruptured tubal gestation. Dr. Boldt said that there were cases where it was absolutely impossible to make a diagnosis. In those cases where one suspected a tubal gestation he advised operating at once, and not waiting.

Dr. GEORGE H. BALLERAY, discussing Dr. Brothers's case, said that in his opinion it was a difficult matter to say when to do an hysterectomy in cases of septic uteri, especially when following an abortion. It was a very difficult matter to formulate any rules for these cases.

Dr. HERMAN J. BOLDT said that it was absolutely impossible to formulate any rules. But where there were evidences of a septic peritonitis, or a general sepsis going on post-puerperal, and where he knew the interior of the uterus to be free from débris, and nothing was to be seen that caused the septic condition, with the patient not getting better in a short time, running temperature of 103°, 104°, or 105°, even if there were no positive evidences from the blood examination that usually meant enlarged and relaxed uterus, in other words, the source of infection in the uterus, the quicker that uterus came out the better. The matter, though, almost always must be left to individual judgment.

Four Specimens of Myofibromata Uteri.—Dr. HERMAN J. BOLDT presented these specimens. The interesting clinical feature of the first tumor was that upon examination it was so soft that several physicians made the diagnosis of an ovarian cyst, although there were irregularities in the menstrual flow, this occurring at intervals of from eight days to three weeks, but only of from three to four days' duration. A steady increase in size of the abdomen had been observed for the past five years. The pathological features of interest were that the center of the tumor showed evidences of degeneration, although not indicative of malignancy. The degenerative change caused the softened condition of the neoplasm. The ovary contained a hematoma, and the ovarian stroma showed fibroid degeneration. The endometrium was fairly normal. The tube walls were atrophic, but their mucosa was normal.

The chief clinical symptom giving rise to the indication for operation in the second case was the existence of constant pain in the lower abdomen for the past four weeks. In addition there were present symptoms of myocarditis. On microscopical examination of the tumor there was slight increased proliferation of the blood-vessels about the periphery, but few blood-vessels in the center of the tumor. Both tubes and ovaries were enlarged, thickened, congested, covered with adhesions and matted matter together. The tubes were thrown into nodes, particularly on the left side, as thick as a lead pencil, and forming a pipe-bowl shape, with the ovaries at the distal extremities. The ovaries were dilated into pus sacs; the broad ligaments were thickened, congested, and board like. It was evident that the chief symptoms were caused by the ovarian abscesses.

The pathological features presented by the third speci-

men were that the interior of the uterus was much enlarged and lined by a thick succulent mucous membrane. The endometritis fungosa caused the atypical bleeding. In some areas the blood-vessels in the mucosa were numerous and much thickened. The blood-vessels in the uterine wall, however, were normal.

The clinical features of the fourth specimen were that the tumor was wedged tightly into the pelvis because of its intraligamentous development on the left side. Pathologically, the tumor was beginning to show degenerative changes in some parts, there being edema present around these areas. The nuclei of the cells did not take the stain, and these and some of the cells were disintegrated. The glandular elements in the mucosa were increased.

Limitations of the Surgical Treatment of Uterine Fibroids.—Dr. Henry C. Coe read this paper. He said that few subjects had been more discussed than that of the surgical treatment of uterine fibroids. His text was furnished by no less than six patients with uterine fibroids, who came to his office within the last fortnight, all of whom had been advised to undergo a radical operation, but Dr. Coe advised against operation. In every instance the so-called tumor was not larger than a small orange, and caused no symptoms, such as pain, pressure, menorrhagia, and was, from his point of view, simply of clinical interest. And yet, these women had been advised to have their uteri removed, even though they were in the prime of life. He wished to call attention to one fact, that confidence on the part of the operator had led to too radical views in dealing with uterine fibroids. He stated that the mere presence of a fibroid was *not* an indication for operation. Excluding cases of fibroids in which the indications, pain, pressure, profuse hemorrhage, steady increase in the size of the neoplasm, evidences of degeneration, complications (local and general), etc., were so clear that the majority of operators would advise operations, he said that he would consider only the class of cases in which there were small interstitial growths, with few if any symptoms, not affecting the general health; in short, these cases which caused the patient no discomfort or disquietude until she had been indiscreetly told that she had a "tumor" He earnestly desired to throw his influence in favor of a higher type of practical gynecology, of a mutual confidence, not only between the specialist and the general practitioner, but between the doctor and his patient He asked why the mere presence of a small uterine fibroid impelled the examiner to inform the patient hitherto in blissful ignorance, but also to advise operation? He found that most of his patients, whom he passed as not requiring even medical treatment, were told that the "tumor would grow," that "it would become malignant," that "it would give trouble at or after the menopause," or the argument had been advanced that the patient had a neoplasm, ergo, it must be removed. It not infrequently happened that he could find no tumor, simply a large hyperplastic or asymmetrical uterus. It behooved the general practitioner to be *sure* that the patient had a tumor before he informed her of this fact, or advised an operation, for once the fatal words had escaped his lips, all the specialists whom she consulted afterwards could not convince her to the contrary. He asked what was the clinical history of the case, and had she any symptoms referable to the increased weight of the uterus, vesical or rectal irritation, displacement of the uterus, interference with the normal function of the pelvic organs? Dr. Coe had been watching many patients from ten to fifteen years with small fibroids, who had never complained of such disturbances. He said he was far from commending the ultra conservative views of those who believed that a patient should be tided over the period of menorrhagia preceding the climacteric under the mistaken idea that the tumor would "disappear" after that time. He did not remember a case in which the fibroid had entirely disappeared after either a natural or artificial menopause, though he had seen it diminish in size and all troublesome symptoms vanish. The whole question of the treatment of uterine fibroids turned on the question of the proper recognition of the variety, the size and sypmtoms caused by the tumor. It was a reproach to their diagnostic and clinical experience if they jumped at the conclusion that surgical treatment was indicated simply because they happened to discover a tumor.

Dr. Herman J. Boldt said that the section was to be congratulated on having had presented to it such an admirable paper on conservatism, and he wished to indorse all except one statement, namely, the question of curettage in cases of myomata. With that exception he endorsed all Dr. Coe had said. He saw no use in removing a uterus, or even operating, when there was simply a fibroid present, especially when it was of small size. If there was an ovarian tumor present, that was a different thing.

Dr. Egbert H. Grandin said that he was entirely in agreement with the statements made by Dr. Coe. He believed that every man with any surgical experience would agree that the mere fact that there was a tumor present was not sufficient justification for its removal. All knew that there was a certain period of a woman's existence when a small fibroid might never become anything more, but they should be able to differentiate surgically their cases. Dr. Grandin said he had used the various methods of treating fibroids. He had been an advocate, and a consistent one, too, of the use of electricity in the treatment of uterine fibroids. He admitted that he had used all kinds of methods, and simply because those who taught him did not know better themselves. Having divested himself of the obsolete methods he had now reached a definite conclusion, as follows: Any fibroid that gave rise to symptoms was a surgical fibroid; if it did not give rise to symptoms, why should any woman then come to him to find out what the matter was? The smaller the fibroid, the less operating, the less strain upon the kidneys and heart, the less size of incision, the greater chance for recovery, the less chance of having an anemic heart, which was associated with increased growth of the fibroid, and, therefore, more hemorrhage. The only class of fibroids that Dr. Grandin feared was the big hemorrhagic ones with the anemic heart, and the tendency to death from so-called shock, etc. The mortality rate from small fibroids which gave no symptoms should be nil; from the large hemorrhagic fibroids it was often 10 per cent. That was his experience. If one let a post-operative fibroid case, hemorrhagic in type, out of bed in three days, there was danger of pulmonary embolism. Whenever a woman had a fibroid which gave rise to symptoms, that fibroid was bound to grow. With regard to the route, any fibroid which could be made to enter the pelvis should be removed by the vaginal route, if one was sure there was no disease of the appendages or of the appendix. Any tumor which could not be made to enter the superior strait above the brim, or where there was a coexistence of tubal or appendical disease, the only route was the one above.

Dr. George H. Balleray said that he decidedly favored conservatism in these cases, and he even went further than Dr. Coe The only indications for the removal of these fibroids were pain, hemorrhage, and rapidly increasing growth of the tumor. Kelly, in his book, had emphasized the fact that the mere presence of a tumor did not indicate the performance of an operation. The conscientious practitioner should show before operating that the tumor was a menace to life or incompatible with the woman's comfort. Fibroids that were not causing symptoms should not be removed. He said he could not plead too strongly for condemnation of this surgery. Such cases as Dr. Coe referred to should not be operated on. Dr. Coe said the statement that tumors or myomata of the uterus would disappear after the menopause was nonsense. But Dr. Balleray had seen such cases that caused such hemorrhage that the patient was tamponed and placed in bed. After a while the tumor ceased growing, and the tumor later disappeared during a retrograde metamorphosis. For that reason he believed that if a woman could safely be carried past the

menopause it should be done. He had known of cases where, after the menopause, the tumors disappeared. He, therefore, condemned what he called unnecessary operating. There might be in some cases a reasonable doubt as to what should be done, and then two men might differ.

Dr. MALCOLM MCLEAN wished to endorse all that Dr. Coe had stated. Certain of these growths were as harmless as a wart on the hand, and no one had any right to remove them when no symptoms were referable to them. Dr. Coe would operate upon those cases if they presented symptoms. If a woman had a small interstitial fibroid she should not consult a surgeon who was willing to mutilate her. He wished to emphasize one point in distinguishing between those cases that should be operated upon and those which should not be. He told his patients that he wanted to see them every three months. When they returned he made careful examination; if he found the tumor was growing, he had them return at a shorter interval; then if he found they still continued to grow, he warned them that an operation was going to come. With regard to malignancy, in all his experience he had seen but one fibroid which apparently degenerated into sarcoma or malignant disease.

Dr. Coe closed the discussion.

Some Further Notes on the Use of Rubber Bags for Dilating the Parturient Cervix.—Dr. RALPH POMEROY showed these bags.

Drs. POLAK and MCLEAN discussed them.

Books Received.

While the MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

ELEMENTS OF PRACTICAL MEDICINE. By ALFRED H. CARTER, M.D., M.Sc. Ninth Edition. 12mo, 614 pages, muslin. H. K. Lewis, London.

THE BACTERIOLOGICAL EXAMINATION OF WATER SUPPLIES. By WILLIAM G. SAVAGE, B.Sc., M.D. (London), D.P.H. 8vo, 207 pages, illustrated, muslin. H. K. Lewis, London.

A MANUAL OF PATHOLOGY. By GUTHRIE MCCONNELL, M.D. 8vo, 523 pages, illustrated, flexible leather. W. B Saunders Co., Philadelphia. Price, $2.50.

A MANUAL OF NORMAL HISTOLOGY AND ORGANOGRAPHY. By CHARLES HILL, Ph.D., M.D. 12mo, 462 pages, illustrated, flexible leather. W. B. Saunders Co., Philadelphia. Price, $2.00.

ATLAS AND TEXT-BOOK OF DENTISTRY, INCLUDING DISEASES OF THE MOUTH. By GUSTAV PREISWERK, M.D., Ph.D., 12mo, 343 pages, illustrated, muslin. W. B. Saunders Co., Philadelphia. Price, $3.50.

MATERIA MEDICA FOR NURSES. By EMILY A. M. STONEY. Third edition, thoroughly revised, 8vo, 300 pages, muslin. W. B. Saunders Co., Philadelphia. Price, $1.50.

THE ELEMENTS OF THE SCIENCE OF NUTRITION. By GRAHAM LUSK, Ph.D., M.A., F.R.S. (Edin.) 8vo, 326 pages, muslin, illustrated. W. B. Saunders Co., Philadelphia. Price, $2.50.

THE IMMEDIATE CARE OF THE INJURED. By ALBERT S. MORROW, A.B., M.D. 8vo, 340 pages, illustrated, muslin. W. B. Saunders Co., Philadelphia. Price, $2.50.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious disease reported to the Sanitary Bureau, Health Department, New York City, for the week ending February 16, 1907:

	Cases	Deaths
Tuberculosis Pulmonalis	356	191
Diphtheria	282	52
Measles	248	6
Scarlet Fever	263	21
Smallpox	12	—
Varicella	91	—
Typhoid Fever	42	12
Whooping Cough	52	6
Cerebrospinal Meningitis	13	13
Malarial Fever	...	..
Totals	1349	301

Pyloric Stenosis Consecutive to the Absorption of Caustics.—Quénu reports the following case: A woman forty-six years old swallowed a concentrated solution of hydrochloric acid. She was taken with acute pain and vomiting. Alimentation became impossible. She became emaciated and entered the hospital six weeks after the accident. Nutrient enemata kept her alive. Quénu determined to practice gastroenterostomy. Chloroform was administered after an injection of serum had been given. The pulse stopped. An incision was made in the diaphragm in order that the heart might be massaged, but the patient succumbed. Autopsy did not reveal severe gastric lesions, but there was a marked stenosis of the pylorus through which a probe could sarcely be passed. This stenosis developed very rapidly, as only six weeks had passed since the time of the accident. In the region of the pylorus the mucosa had disappeared.—*Gazette des Hôpitaux Civils et Militaires.*

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine-Hospital Service, during the week ended February 15, 1907:

INFLUENZA IN ITS RELATION TO DISEASES OF THE NERVOUS SYSTEM.*

By JOSEPH COLLINS, M.D.,

NEW YORK.

PROFESSOR OF NERVOUS AND MENTAL DISEASES AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL, VISITING PHYSICIAN TO THE CITY HOSPITAL; NEUROLOGIST TO MONTEFIORE HOME, CONSULTING NEUROLOGIST TO THE HOSPITAL FOR RUPTURED AND CRIPPLED, AND TO THE MANHATTAN STATE HOSPITAL, WEST.

The bacillus of influenza and the poison engendered by its active existence in the body, have a peculiar capacity to disorder the functions of the nervous system, and to cause pathological changes in its central and peripheral portions. The truth of this has been especially recognized since 1890, *i.e.* since the occurrence of the last epidemic of influenza in this country and in Europe. To convey an idea of the literature that has been created setting forth the nervous sequelæ of influenza, it may be stated that the references alone to the subject take up five closely printed pages of nonpareil type of the Index Medicus. There is scarcely a disease, functional or organic, of the brain, cord, or peripheral nervous system, that has not had its causation attributed to influenza, and I may add, in many instances, quite improperly. One does not attribute acromegaly to an occasional inebriation, especially if the symptoms do not develop for some time after the indulgence. No more should conditions of absolutely unknown causation, such as paralysis agitans, or of fairly well-known origin, such as exophthalmic goiter, be attributed to an attack of influenza, out of which apparently flowed no symptoms whatsoever save those of the infection, and which terminated in recovery.

The period during which influenza has been studied scientifically corresponds to that of my special interest in nervous and mental diseases. When it first prevailed I was in active general practice, but soon after that began to see nervous disorders in one of the large clinics of this city. Since that time, and particularly during the past ten years, I have had opportunity to study nervous diseases, which has permitted me to gather the records of upward of ten thousand patients, personally examined. It is largely upon a study of these records that the statements and conclusions embodied in this paper are based. In order to make the statement as emphatic as possible, I shall say in this connection that this experience teaches me not to share the view of those who maintain that influenza is a common or important cause of nervous or mental disease, either functional or organic; common, I mean, in contrast with such causes as syphilis and alcohol. I do not wish to be understood as underestimating the disastrous effects that follow successful attack on the nervous system by the bacillus of Pfeiffer. They are often very severe, and that they do occasionally occur everyone admits. That which I wish to show is that they occur infrequently.

As an example of the indiscriminate accusation of influenza as a cause of death without the production of definite disease, statements from the literature like the following, which, by the way, is not unique, may be quoted: Dr. E. A. Cobleigh[1] of Chattanooga says: "Some patients (after influenza), wholly without regard to age or previous vigor, were too feeble for any movement or exercise beyond the minimum of vitality required to stay alive. This one element of debility was profound, and the sole cause for uneasiness. Instead of recovering within ten days or a fortnight, most of these sufferers lingered for weeks, sometimes even for months, and not a few dwindled on for a year or two, to die of sheer exhaustion at last." One of the most impressive and rare complications that he recalled ever having seen, consisted in extreme clonic, spasmodic seizures, particularly involving the heart, the diaphragm, and the muscles of respiration, with no mental disturbance except the most pitiable fear of impending death. Nor do I in any way subscribe to the following sentiments expressed editorially in the Medical Record, August 13, 1904: "If an individual, through the sins and misfortunes of his fathers, inherits a predisposition to any disease, an attack of influenza will in most instances develop this disease. This statement is especially true of affections of the nervous system, and renders, in these times, influenza a malady greatly to be dreaded. Considered from almost all points of view, influenza is perhaps the most deadly disease to which the modern individual is subject. When it does not kill, it either cripples or leaves the victim of its onslaught a worse man physically and mentally than he was before the attack." Surely, there is no justification for such animadversion, else I should have been brought face to face, professionally and socially, with many of these wrecks! Why see red and blue so vividly when the real causes of nervous and mental diseases, syphilis, alcohol, and narcotics, take their iniquitous way almost unmolested?

I can scarcely hope to do more in the fifteen minutes allotted me, than barely to outline the relationship of influenza to diseases of the nervous system. Statistics will appear in the published article, and recitation of cases would not enhance the value of my remarks.

In a general way, it may be said that influenza causes chronic disease only by causing disorder of the nervous system and of the special senses. The best evidence of the truth of this statement is the fact that influenza, a well-defined disease of the latter middle ages and a ravage of the nineteenth century, was entirely forgotten and had practically lost its place in medical literature, until the epidemic of 1890, when disorders of the nervous system had become diagnosticable, and neurology the most important integral part of general medicine.

The bacillus of influenza may and does cause

* Read at a meeting of the New York Academy of Medicine, February 7, 1907.

meningitis, encephalitis, myelitis, and possibly neuritis. The toxins produced by the pathogenic activity of the influenza bacillus are adequate exciting causes of neurasthenia and psychasthenia, of neuritis and neuralgia, of various forms of insanity, of independent nervous symptoms, such as insomnia, vertigo, headache; and they may be contributory to the causation of any disease that afflicts the human being. This practically constitutes the accusation against influenza from the neurologist's standpoint. But I repeat neither the bacillus of Pfeiffer nor its toxins, *i.e.* influenza (if what is called influenza is the equivalent of the existence in the system of these two things), is a common cause of nervous disease. I take for granted that it may be assumed that much that is called grippe by the patient and physician is not influenza in the strict sense.

The most serious diseases of the nervous system caused by the bacillus of Pfeiffer are inflammations of the central nervous system and its covering—encephalitis, myelitis, and meningitis—all extremely rare and extremely serious complications of influenza. There is very little in the clinical manifestations of these various diseases that permits the physician to distinguish them from those caused by other organisms. Since the utilization of spinal puncture and examination of the spinal fluid as a routine diagnostic measure, many cases of influenzal meningitis have been recognized. Before that time the bacillus of Pfeiffer had been found in the exudate of certain cases of meningitis.[2] In many cases it occurs accompanied by other organisms. Recently J. S. C. Douglass[3] has reported a case of influenzal meningitis occurring in a female patient ten months old, whose cerebrospinal fluid obtained during life by a lumbar puncture, showed many bacilli situated both intra and extracellularly, of the shape and size of Pfeiffer's organism. After death a similar bacillus was found in the meningeal exudate. This case, taken in conjunction with those reported by Nuthall and Hunter,[4] Judson Bury,[5] Thomesca and Gracoski,[6] and Mya,[7] adequately proves that meningitis may result from this bacillus. Whether or not influenzal inflammation of the meninges is ever a primary infection, I mean infection by the bacillus, is not known. One can infer that the infection is a primary one in the absence of symptoms pointing to involvement of the nasopharynx, the adjoining sinuses, of the middle ear, and of the respiratory system.

So far as I know, there is nothing in the clinical manifestations of meningitis, cerebral or spinal, which permits one to say whether or not it is due to the bacillus of influenza. It may be presumed to be of such origin when it occurs in the wake of influenza at a time when influenza is present, or when it is sequential to disease of any of the cavities about the head caused by influenza, but it can be positively so characterized only when the bacillus of Pfeiffer is found in the cerebrospinal fluid. Here it should be said that it has frequently been pointed out that, although the cerebrospinal fluid at the first puncture does not contain the bacilli, often a second or third tapping may reveal them. Cases of well-marked meningitis that end in recovery always excite a suspicion in the mind of the physician who sees the common terminal results of meningitis on the post-mortem table, that possibly the case was an example of what the French call pseudomeningitis, or meningisme, a condition which may be best described negatively as one due not to the activity of the pathogenic organism directly, but to its toxins, and in which after death there is found only hyperemia and possibly increase of serum. While I have seen cases of meningitis apparently typical and fully developed in every way, occurring in the wake of influenza with catarrhal manifestations in the mucous membrane, terminate in recovery, I have never seen such a case in which the bacillus of Pfeiffer alone was found.

Influenzal meningitis occurs, as all other forms, more frequently in children than in adults. In twelve cases reported by Ghon,[8] with post-mortem examination, there were eight children and four adults.

Acute nonpurulent encephalitis, meaning, as a rule, hemorrhagic focal inflammation of the cortex (often of symmetrical areas in each hemisphere), is a disease that has received recognition only during the past few years. Its causation, its clinical display, and its terminations, are now fairly well understood. That the bacillus of influenza causes it, there is no doubt. That it has been and is still often diagnosticated as meningitis, is a fact. That its chief symptoms are headache, vertigo, irritableness, and stupidity, quickly leading to delirium and unconsciousness, with comparatively slight constitutional manifestations, and often unaccompanied by signs of cortical irritation or destruction (spasms, aphasia, or paralysis), all writers are agreed. Particular symptoms indicative of the exact location of the focus of inflammation occur only when a highly specialized area of the brain, such as the Rolandic area, the speech area, the cuneus, etc., is the seat of the disease. That the life of individuals that have even severe attacks of this disease is often spared, and that many such cases are later labeled cases of infantile cerebral palsy, organic epilepsy, sclerosis of the brain, hydrocephalus, idiocy, etc. (and that, therefore, it may be truthfully said that such diseases or conditions have a genetic relationship to influenza), can easily be demonstrated. Although the occurrence of this disease in the wake of influenza is good evidence that influenza is responsible for it, and although this evidence is corroborated by finding the bacillus in the tissues of cases that have terminated fatally, it is more difficult even than in meningitis to say that such and such a case is due to the influenza bacillus. That such is the case may be suspected and inferred from its association. The cerebrospinal fluid may reveal the organism, but I do not find any case recorded in which it was found during life.

Acute hemorrhagic encephalitis is a diagnosis that was made fourteen times in my clinic last year. During this period 1,532 patients sought relief from disorder of the nervous system. One may or may not gather from this an idea of its frequency. I believe it to be of more frequent occurrence than is commonly supposed. I have had no experience that leads me to share the belief of some writers, that a disseminated encephalitis (which later in life becomes the anatomical basis of chronic organic chorea, or disseminated sclerosis) is a sequence of influenza, although a few such cases are recorded. The gray matter within the brain may likewise be attacked by the bacillus of influenza or its toxins, and the clinical picture of polioencephalitis superior and inferior (Oppenheim-Uhthoff) result.

Naturally, the cerebellum may be involved as well as the cerebrum and the brain ganglia. What the symptoms of such involvement are will depend upon so many factors (part of the cerebellum involved, intensity and extent of the lesion, etc.), that it is difficult to particularize them. A case reported by Guttman,[9] under the title of "Brain Paralysis After Influenza," may, however, be taken as an excellent example of influenzal cerebellar encephalitis, al-

though there are many symptoms, such as the beginning ones, that tend to indicate that there was a widespread infection. Four weeks after the beginning of the influenza, the patient complained of weakness of the right leg, tenderness of the calf muscles, and later of pain and weakness of the right arm. Two months later both legs were weak, and his gait was unsteady. At this time he complained mostly of vertigo and of headache. Shortly afterward the right eye went into a state of convergent strabismus, and examination showed that it could not be moved out of that position. The right facial nerve was weaker than the left; there was intention tremor of the right hand, and the tendon-jerks were much exaggerated. The patient recovered completely after six months. The ocular palsy and nystagmus, the tremor of the hands and feet, the exaggerated reflexes and ankle-clonus, all point to its being an inflammation of the cerebellum.

The occurrence of myelitis after influenza was soon recognized after the epidemic of 1890. The published histories of many patients show that such myelitis displays itself in one of three forms: as a transverse or as a punctate disseminated lesion, and as an acute systemic involvement, the motor tracts being particularly involved, to constitute a clinical syndrome resembling that of acute ascending paralysis, or Landry's paralysis. In exceptional instances the symptoms display themselves in a way that indicates that the morbid process is a meningomyelitis. The feature of influenzal myelitis that calls for comment, and the one that sets it apart from other varieties of myelitis, is its termination, which, in not a few instances, has been in complete recovery. There are many such cases on record. Personally, I have seen but one. In this case the only sign at the present time that the cord did not entirely regain its normal state, now five years after the occurrence of the disorder, is liveliness of the knee-jerks. In other instances the termination is in partial recovery, the clinical condition remaining corresponding to that of lateral or combined sclerosis. Cases have been recorded to show that in some instances following upon grippe the spinal cord becomes diseased in what may be called a subacute way, the clinical accompaniments being those of subacute spastic paralysis, or acute spasticity and spinal paralysis, such as the case reported by Henschen,[10] in which a man thirty-four years old had the typical symptoms of this condition, which terminated in recovery. A similar case has been recorded by Koster.[11]

That influenza exerts a profound poisonous effect upon the nervous system, which effect is continuing after the disorder itself has disappeared so far as any evidence of its active existence can be made out, was known long before the bacillus of influenza was discovered by Pfeiffer. The poison which the activity of the bacillus produces is capable of bringing on inflammatory or degenerative processes, at least in the peripheral nerves and in the muscles, to produce neuralgia, myalgia, and multiple neuritis, and this I have spoken of in another part of this paper. They are not more striking, however, than individual symptoms, particularly insomnia and headache, which follow in the wake of grippe. Of all the sequelæ of grippe, I know of none which is more distressing and more persistent than these. It has been suggested that they are dependent upon cerebral hyperemia, or on change in the meninges, such as meningeal and cortical edema, but this seems to me an utterly unnecessary hypothesis, and a much less likely one than that which attributes them to alteration of blood-pressure in response to the action of the toxins upon the blood vessels. Naturally, as we know not how sleep is caused, we cannot very well know how it is disordered, even though we may be able to give full enumerations of the things that disorder it. That it is disordered after influenza is very well known, and that to relieve it very often requires a therapy directed against circulatory disturbances, evidences of impaired metabolism and nutrition, and toxemic conditions, as well as the utilization of hypnotics. In other words, tonic baths, massage, sweat baths, eliminants acting through the intestinal and renal tracts, as well as veronal. What is here said in reference to the post-influenzal insomnia applies with almost equal force to the treatment of post-influenzal headache.

One of the most remarkable associations of the clinical symptoms which influenza produces, is that of bulbar paralysis of the asthenic variety. It may be permitted me to say that there is a form of bulbar paralysis which has certain typical clinical characteristics, in which after death no lesion of the oblongata has been found, and to which the name asthenic bulbar paralysis has been given. This condition has been noted to occur after grippe, but whether the influenza is a contributory cause or an active exciting cause, cannot be said. In a case reported by Pitres,[12] the case seems to be a general asthenia more than a bulbar asthenia.

Disorders of the nervous system that in my experience stand most frequently in causative relation to influenza, are those dependent not upon the direct action of the bacillus of influenza upon the nervous system, but upon the activity of toxins produced by the pathogenic activity in these germs. These are neurasthenia and psychasthenia, neuralgia and neuritis, and diseases and disorders of the nervous system attending and depending upon arteriosclerosis.

That after grippe many individuals are enfeebled mentally and physically, out of keeping with what has seemed to be comparatively a simple preceding febrile disorder, there can be no doubt. Just how much depression, apprehension, inattentiveness, insomnia, and impaired physical vigor one must have before he is entitled to label the individual neurasthenic or psychasthenic, no one can say. Nor does it aid us in the successful recognition or treatment of such condition so to label it. It is probably far better for both patient and physician if such cases that terminate in recovery under appropriate treatment at the end of a few weeks are not thus labeled. No one thinks of designating similar conditions following typhoid fever, rheumatic fever, and lung fever, as neurasthenic and psychasthenic, and probably because in such instances the severity of the preceding disease seems to be adequate for such entailment as exists, but the fact that the phenomena of grippe are often so slight in their severity and brief in their existence, makes it seem incredible that such preceding effects may be the result, but one only has to recall the gravity and innocuousness of the infection of anterior poliomyelitis and compare it with the sequelæ to have a parallel. Occasionally, but not very often, it is my belief, there develops after influenza (perhaps oftener than after any other disease caused by a germ whose tendency it is to find its most favorable development in some mucous membrane) mental, nervous, and visceral symptoms, which are properly designated psychasthenia and neurasthenia. The one most characteristic feature of these cases is that they are hypochondriacal. The anxiety type, the obsessional type, the self-accusatory type, and other well-known forms, are rarely displayed. In these severer forms the profound bodily weakness manifested in great

fatiguability and symptoms indicative of collapse on comparatively slight effort, are sometimes noted. They bespeak, as do the severer forms of neurasthenia and psychasthenia, either a profound intoxication of the system or an extremely vulnerable cerebrospinal organism. In these cases, as in the psychoses, the intensity of the symptoms of these nervous disorders does not seem to be proportionate or in any way connected with the intensity of the phenomena caused by the infection itself. In other words, a very mild attack of grippe is sometimes followed by a profound attack of nervous prostration, but then this is not unlike that which experience has taught us is common for other post-infectious involvement of the nervous system, for instance, after diphtheria.

Many cases of post-influenzal hysteria have been recorded, but what is said regarding the relationship of insanity to influenza holds good as well for hysteria. Hysteria does not occur after influenza, save in individuals who have a psychopathic or neuropathic foundation. In such individuals, hysteria may develop or other pathological mental states may follow, depending upon conditions which are imperceptive to the average mind, upon conditions that indeed are considered far too inadequate and entirely too trifling, but the pathogenesis of the hysteria in these cases is the pathogenesis of hysteria in general.

Post-influenzal neuritis, either of a single nerve or of many nerves, is a well-recognized condition. Influenzal multiple neuritis is fairly uncommon, *i.e.* compared with alcoholic, rheumatic, and gouty neuritis. Any of the nerves of the body may be involved apparently. Henschen has reported a case of bulbar neuritis, in which the symptoms were quite typical of this variety of bulbar palsy. That the spinal ganglia are sometimes the seat of an inflammatory or degenerative condition growing out of grippe, is testified to by the numerous cases of herpes zoster to be found in the literature. That brachial and sciatic and generalized multiple neuritis occurs, there is no dearth of testimony. The motor nerves seem to have a greater susceptibility to the action of the toxins produced by the Pfeiffer bacillus than the sensory nerves, but the same holds true for almost every variety of infectious neuritis, of polyneuritis, unless it be that rheumatism is the exception to this rule. Still, we are not at all sure that neuritis follows so frequently in the wake of that form of rheumatic fever which is due to a diplococcus rheumaticus, as it does in the wake of disorders called rheumatic which are dependent upon deficiencies of metabolism, and neuritis dependent upon alcohol, which are predominantly sensory and sensori-motor in their manifestations. The one point that has been impressed upon me in connection with the neuritides of influenza is that their duration is much briefer than apparently similar conditions dependent upon other causes. For instance, I have seen a patient with extensive multiple neuritis, causing quadriplegia, recover within six months. A similar condition, due to alcohol, would pursue a favorable course if it recovered in twice that time. This fact, and likewise a less important one, viz., that the atrophy attending post-grippal neuritis is in some instances not very profound, suggests that the lesion is oftentimes a perineuritis rather than a parenchymatous process.

To the neuralgias following grippe, I shall have little to say, first, because there is nothing specific about them, and second, because post-toxemic neuralgias are extremely uncommon. They are much more liable to occur in individuals who are in impaired health and when overtaken with grippe, and in women, particularly those who are afflicted with constipation and indigestion. In certain cases of trifacial neuralgia it is probable that the influenza infection has been the exciting cause of degenerative changes in the cells of the Gasserian ganglion, and in this way is to be looked upon as an important contributory cause. The duration of the ordinary neuralgias, whether occipital, facial, brachial, or crural, is usually brief, though now and then we encounter an example that is most rebellious to treatment. In such cases there is likely to be an underlying condition of ill-health that accounts for it.

One of the most interesting phases of this question, *i.e.* the relation of disease and disorder of the nervous system to influenza, is reached when we attempt to discuss the relationship of diseases of fairly well-defined cause on the one hand, and of absolutely unknown cause on the other hand, to influenza. Such diseases as tabes, syphilitic spinal paralysis, and the various forms of cerebral apoplexy, on the one hand, and disseminated sclerosis, amyotrophic lateral sclerosis, paralysis agitans, asthenic bulbar paralysis, etc., on the other hand. Those who have given serious study to the question of the cause of tabes may differ as to whether or not syphilis is the *sine qua non* of that disease. But it can scarcely be maintained by anyone that influenza is an adequate cause of tabes. The literature shows that such allegation has often been made, and the same may be said of the other diseases that have been enumerated. One of the typical cases of that form of myelitis or meningomyelitis which has been spoken of as Erb's type of syphilitic spinal paralysis, that I have ever seen, developed in a young man a few weeks after a comparatively severe attack of grippe. It may well be that in this case the individual, coping with as much poison as he could take care of, viz., the syphilis, had his nutrition, or the circulation, of his spinal cord so depreciated that the pale spirochete produced the typical pathological reaction there. But in this case the disease had its origin in syphilis, and would have developed probably in a similar way after any devitalizing experience.

I have recently watched the development of a profound generalized arterial sclerosis, and finally cerebral thrombosis, in a young man of thirty-six, the victim of Hanot's cirrhosis. Apparently the arterial sclerosis had developed within a period of five months, the time corresponding to the duration of the jaundice. At least, it may be said that the diagnostic features of the disease have developed within that time. That which the cholemia (to give it a name) has accomplished in the vascular system, for this man is comparable to that which the toxins of influenza do for a few, and just as the Hanot's cirrhosis has been the cause of cerebral apoplexy in the case that I mention, so is influenza the cause of some chronic nervous disorders, by mediating changes in the arterial system.

The relationship of psychoses to influenza has an enormous literature all its own: still, it is possible to summarize a knowledge of the subject in a few lines. There is no specific influenza-psychosis, and no form of insanity that is particularly likely to be called into existence by influenza. Individuals who are liable to develop insanity, *i.e.* those who are laden hereditarily and those who are debilitated by alcohol and syphilis, are more likely to develop a psychosis if they have influenza than if they have not. In this way influenza may be said to stand in relationship to manic-depressive insanity, general paresis, confusional states, and possibly even dementia precox. It is undeniable that psychoses

sometimes develop after influenza in individuals who have neither hereditary nor neuropathic taint, but so likewise does insanity, not preceded by influenza. Psychoses develop both during the prodromal stage, the febrile stage, and after the influenza has ceased to exist as a disease, causing general symptoms, *i.e.* in the stage of convalescence. It seems legitimate to believe that the psychosis immediately preceding and during the active stage of influenza is dependent upon the action of the toxins upon the cerebral cortex, and in these instances the psychosis is apt to be of the nature of acute delirium. There are cases on record in which this acute delirium has been very profound, and terminated fatally within a few days, and in such instances there can be no doubt but that the action of the toxins upon the brain is to produce an acute hemorrhagic inflammatory condition. In the cases that develop after convalescence of the disease the mental condition is probably the expression of the effects of the toxins upon the cortical nutrition, and likewise upon the nutrition of the entire system, and are to be looked upon as a combination of causation and intoxication.

It has been pointed out by many that there is no relationship between the severity of the attack of influenza and the insanity which accompanies or follows it. Oftentimes the most severe mental disorder may occur soon after or apparently in connection with a light attack of influenza.

In conclusion, I say again, that experience teaches me that the baneful effects of the pathogenic activity of the Pfeiffer bacillus upon the nervous system have been overestimated, and that in reality influenzal and post-influenzal neuroses and psychoses are not very common. Finally, I trust that this statement may not be considered as a denial of their occurrence.

THE RELATION OF THE TONSIL TO INFECTION AND INFECTIOUS DISEASES.*

BY ROBERT CURTIS BROWN, A.B., M.D.,

MILWAUKEE, WIS.

LECTURER ON GENERAL ETIOLOGY AND HYGIENE, WISCONSIN COLLEGE OF PHYSICIANS AND SURGEONS; PHYSICIAN TO THE MILWAUKEE COUNTY HOSPITAL, THE CHILDRENS' FREE HOSPITAL, AND THE MILWAUKEE MATERNITY HOSPITAL.

THE tonsils may be described as two elongated, almond-shaped masses of lymphoid tissue situated one on each side of the fauces between the anterior and posterior pillars. They present on their outer surfaces eight to twelve orifices which lead down to blind pockets or crypts. If the tonsil of a rabbit, which consists of a single mass of lymphoid tissue, be taken as a type, the human tonsil is composed of eight or twelve such masses bound together so that the mucous membrane covering each mass forms the lining of the spaces between them, which are the tonsillar crypts. This arrangement of reduplication increases enormously the surface of the tonsil. The embryonic formation of the crypts is very interesting. The tonsil is at the border line of the epiblast, which forms the lining of the mouth, and the hypoblast, which forms the alimentary canal. Reterer, in his "Evolution of the Tonsil," shows that the epiblast folds into the hypoblast and the epithelial cells become more and more flattened from pressure. Some of them undergo degeneration and, being thrown off, leave the spaces which are the crypts. The tonsil afterwards becomes infiltrated with mesodermic cells. The mucous membrane in common with that of the mouth consists superficially of flattened epithelial cells. Beneath the flattened epithelium the cells become more rounded

FIG. 1.—Diagram showing the encroachment of the lymph follicles on the mucous membrane at the bases of the crypts.

and then polyhedral, resting upon a single layer of columnar cells. Underneath the epithelium is a delicate endotheloid basement membrane. The mucosa beneath the basement membrane consists of interlacing bands of connective tissue which, though very fine in the normal tonsil, becomes immensely hypertrophied in chronic disease. Bands of connective tissue extend from the mucosa into the interior of the tonsil and form the framework for the adenoid tissue proper. This consists of masses of lymph corpuscles grouped into follicles surrounded by lymph spaces. The follicles, 10 to 12 of which surround each crypt, encroach on the mucous membrane at their bases. The lymph corpuscles are small round cells, each having a distinct special nucleus surrounded by a mass of protoplasm. The unexposed portion of the tonsil has a firm connective tissue sheath and the vessels enter through it at the base. The blood supply of the tonsil is very large and is derived from the dorsalis linguæ, the ascending palatine and tonsillar, the ascending pharyngeal and descending palatine arteries. The principal vessels enter the base, branch, and follow the connective tissue framework. Their capillaries anastomose in an aborescent manner about each follicle; branches are also sent to the papillæ of the mucous membrane. Superficially the tonsil is covered with an enormous network of lymphatic vessels which anastomose with the surrounding lymphatics of the palate and tongue. In the deeper portion they have been shown by Reterer to commence in the perifollicular spaces by a system of

*Read before the Milwaukee Medical Society, December 11, 1906.

closed canals and leave by the efferent vessels at the base. The tonsil is abundantly supplied with racemose mucous glands which communicate with the crypts and exposed surface of the tonsil. The nerves are derived from the fifth and glossopharyngeal, their minute distribution is not definitely settled, but they probably terminate in the lymph follicles. The lymph follicles of the tonsil are very similar in structure to the malpighian corpuscles of the spleen; however, the arrangement of the blood supply is different. In the spleen the lymph cells are grouped around the terminal capillaries in masses, while in the tonsil the masses of lymph cells are surrounded by the blood-vessels. The tonsillar arrangement, I should think, would favor the more ready escape of leucocytes from the vessels, which fact we will see is of great importance in the function of the tonsil. New lymph cells result through the multiplication and division of lymph corpuscles

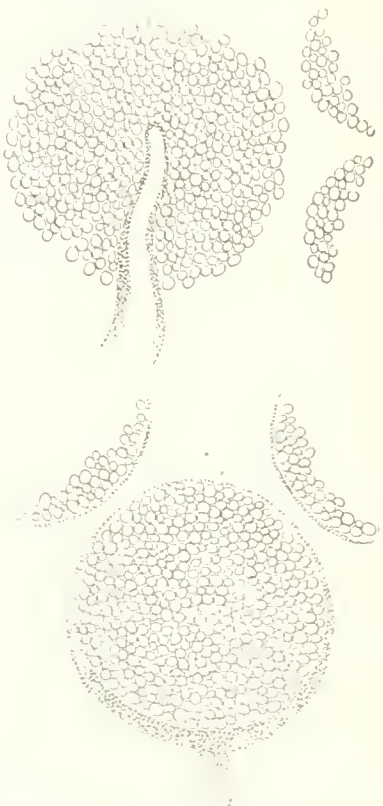

FIG. 2.—Diagram showing the arrangement of the blood supply of the malpighian corpuscle of the spleen (A), and the lymph follicle of the tonsil (B).

and likewise of the so-called fixed connective tissue cells, as has been demonstrated with certainty, especially in inflammation. They are continually entering the lymph spaces to be taken up by the blood-vessels or to be carried away from the tonsil by the efferent lymph channels. Some of them, especially from the follicles near the surface, enter the crypts. During inflammation of the tonsil the number entering the crypts is enormously multiplied. Just as there is an entering of lymph corpuscles into the blood-vessels to become leucocytes, so is there a wandering from the blood-vessels of leucocytes which enter the tissue of the tonsil whose loose structure facilitates their movements. Many of them also find their way into the crypts, especially during inflammation.

The cavity of the mouth is very much exposed to microbes which enter with the food and external air. Miller has recognized in man more than thirty species. Several, such as leptothrix and spirochete, are constantly present; with them are also frequently found pneumococci, staphylococci, and streptococci, whose pathogenic powers are well known. Virulent diphtheria bacilli are also found in the throats of a certain number of quite healthy persons. The Massachusetts Associated Boards of Health found that the Klebs-Löffler bacillus was present in the throats of from 1 to 2 per cent. of all healthy persons and in 8 to 50 per cent. of those who had been exposed to diphtheria in families. In spite of these facts many persons, though exposed, escape infectious diseases, and wounds of the mouth heal very rapidly. Operations, even though done without aseptic precautions, are usually not followed by infective complications. How does the mouth defend itself against so many microorganisms? Sanarelli came to the conclusion, after extensive researches, that saliva had an antiseptic power and destroyed the microorganisms. Hugenschmidt, working in the laboratory of Metchnikoff, reaches conclusions quite at variance with Sanarelli. In his experiments, the microorganisms grew rapidly in saliva. It has, however, a mechanical effect similar to the lacrymal secretion, and washes the microorganisms from the pharyngeal cavity into the stomach. It has another indirect action, that of effecting a positive chemotaxis on the leucocytes, which fact has been proved by introducing capillary tubes containing saliva into the peritoneum of guinea pigs; leucocytes attracted by the saliva entered and digested the microorganisms in it. The flattened epithelial cells covering the buccopharyngeal cavity constitute an important protective factor. The cells are being constantly renewed. Desquamation, taking place especially during mastication, carries away innumerable germs which are on their surface and in the interstices. There is a partial renewal of the epithelial lining after every meal. The mouth, in common with the rest of the digestive system, is furnished with a defensive apparatus against microorganisms in the shape of lymphoid tissue, viz., the lymph follicles at the base of the tongue and the tonsils. Some years ago Stöhr demonstrated that the tonsils are traversed by enormous numbers of leucocytes, which migrate into the cavity of the mouth. This continual and normal condition is called Stöhr's phenomenon. When a particle of mucus is removed from the surface of the tonsil of a person in good health, we always find that it contains leucocytes, the neutrophile cells especially being filled with organisms of all kinds.

Formerly inflammation was looked upon by pathologists as always of a destructive and harmful nature. Recent bacteriological research has demonstrated, on the contrary, that it is of a protective character, being Nature's means of limiting the advance of noxious microorganisms. It is to Metchnikoff, who in 1883 issued his work on the comparative pathology of inflammation, that we owe our present knowledge of the protective reactions of the human organism. Virchow had advocated the nutritional theory, namely, that there was an increased flow of nutritive substances to the inflamed part, as well as an abnormal proliferation of local cells; in fact, that inflammation began from the moment nutritional derangement occurred. This derangement consists of an absorption or modification of large quantities of nutrient substances. In this way the cells receive a large amount of nourishment at the expense of the blood. Virchow regarded the characteristic phenomena of inflammation not as a salutary means of reaction, but as a process dangerous to the organism. Samuel and Cohnheim held that inflammation consisted in

a molecular lesion of the vascular walls of the blood-vessels, which lost their power of retaining the blood corpuscles, allowing them to issue to the places of least resistance. Metchnikoff shows that, from the point of view of comparative pathology, inflammation is essentially reactive in nature. The organism, threatened by some injurious agency, protects itself by the means at its disposal. The lowest organisms struggle against morbid agents instead of submitting passively to their attacks. The essential factor in inflammatory reaction is an endeavor on the part of the protoplasm to digest the harmful object. In the lowest forms of life the whole organism takes part in the digestion, but from the sponges up the digestion of the morbid agents is confined to the cells of the mesoderm. The phagocytic action is slow in the lower scale of life, for the cells have to depend entirely upon their ameboid movements to reach the injurious body; but as soon as, in the course of evolution, a vascular system makes its appearance, the phagocytic reaction becomes more rapid. By means of the circulatory apparatus, the organism can send the defensive cells to the threatened point in large numbers. When the circulation is partially carried on by a lacunar system, there is nothing to intercept the movements of the cells toward the seat of the injury; but if the cells are inclosed in blood-vessels, they must pass through the vascular walls by diapedesis. In man the principal cells, which have phagocytic action, circulate in the blood. They are the neutrophile cells which Metchnikoff calls the microphages and the large mononuclear cells which he designates as the macrophages. They are able to digest by intracellular ferments called cytases. In cases of natural immunity the cytases rid the body of microorganisms without the cooperation on the part of other soluble ferments; in acquired immunity there are other substances called fixatives, which, though not bactericidal, render the microorganisms more susceptible to the action of the cytases. The cytases are allied to the proteolytic disastases in that they adhere to the cells which produce them; the fixatives, however, though undoubtedly of cellular origin, pass readily into the fluids which bathe them. No less important in phagocytic reaction are some of the fixed tissue cells, for instance, the endothelial cells of the blood-vessels which, by their sensibility and contractile properties, allow the phagocytes to escape through the vessel walls. Another form of sensibility which must be mentioned is that of the nervous system, which aids the cells and the vascular system in their efforts at resistance. The action of the macrophages and microphages is well seen in the case of an immunized horse inoculated with streptococcus serum. In the local edema caused at the site of inoculation, the phagocytosis may be observed. In this case the macrophages or mononuclear cells first appear and devour the cocci; in many cases the cocci multiply rapidly within the macrophages, and, having overcome them, escape in large numbers from their bodies. Later the microphages or neutrophile cells come to the rescue of the macrophages and commence to englobe and digest the cocci until in a few days there are none left.

I do not wish to go too deeply into the different varieties of tonsillar inflammation, but I will point out certain facts which determine the character of the inflammation and give some examples. An inflammation of a mucous membrane may be catarrhal, croupous, or diphtheritic. We must also consider the irritant and its virulence, the amount and character of the tissue involved, and its power of resistance. The peculiar anatomy of the tonsil determines its appearance when there is much reaction on the part of the organism. In the disease called mycosis we have a fungus-like growth on the tonsil produced by an irritant, namely, the leptothrix, which is able to induce no inflammatory reaction to speak of, there being simply a multiplication of the bacillus on the soil where it has chosen to locate. The streptococcus, on the other hand, if sufficiently virulent, is able to produce a violent inflammatory reaction in the tonsil. It also has the power to cause the tissue cells to release a fibrin ferment, which accounts for the formation of the pseudomembrane. A virulent Klebs-Löffler bacillus overwhelms and destroys the cells and so rapidly permeates the tissue that necrosis is produced. This accounts for the adherence of the membrane. In all forms of infection, with a few exceptions, there is a reaction on the part of the tonsil which is usually described as acute follicular, or better, lacunar tonsillitis. Professor Fraenkel describes the clinical picture as follows: "The tonsils and adjacent tissues are red and swollen. The tonsils particularly project prominently into the mouth and on the surface, which is more uneven than it usually is; there are points of white, which a little observation shows to be rounded drop-like projections of a viscid whitish substance. After the patient swallows, the whitish points disappear for a time or show only slightly and not so numerous as before; but if you watch the tonsils for a few minutes they appear again and grow gradually larger. When they are removed by the act of swallowing, you can see that they were situated on the so-called crypts of the tonsils, the little infoldings of the superficial mucous membrane of the tonsil that occur all over the organ." A microscopic examination shows that the exudation consists of fine fibrillæ, interlaced and containing in their meshes epithelial cells, leucocytes, red blood-cells, lymph corpuscles, and bacteria, many of these last being within the cells.

What has taken place in the tonsil? Under the stimulation of a morbific agent phagocytosis has commenced. There are always normally a large number of leucocytes wandering toward the periphery of the tonsil and escaping through the crypts. As we have said before, these, if examined, will be found to be phagocytes, often containing bacteria. As a result of increased phagocytosis the microphages and macrophages are attracted to the tonsil in large numbers and wander out more plentifully. The result is the approach to the surface of the mucous membrane of large numbers of cells. This does not mean the exposed surface of the tonsil; for, as we have shown, the mucous membrane lines the crypts entirely, so that the major portion of the mucous membrane of the tonsil is within the crypts. This, together with the fact that the adenoid tissue encroaches on the mucous membrane at the bottom of the crypts, is the reason why the exudation is first formed there and, accumulating, is continually filling up the crypts and escaping from their orifices. Bosworth, in his work on the diseases of the nose and throat, misses the point entirely when he says that he knows of no reason why the catarrhal inflammation should be confined to the crypts and offers the suggestion that, because the secretion is friable and non-adherent, it is washed from the surface of the rest of the tonsil. The fact is that the exudation is formed in the crypts, and it is the exit of the leucocytes carrying with them the bacteria that have

found their way into the tonsil, together with the cast off epithelium and other débris, that constitutes the distinctive feature of the disease. The red and swollen appearance of the tonsil is due to the increased blood supply.

What is the fate of pathogenic germs that may happen to find lodgment on the tonsil? They may be washed off by the saliva. They may be carried away by the desquamation of the epithelial cells. If they should attempt to enter the crypts they may be mechanically washed out by the mucous secretion and the lymphocytes, or be devoured by the phagocytes which are continually passing out of the crypts. If the bacteria are present in sufficient quantities to call forth further defensive action, phagocytosis occurs, the lymphocytes in the follicles rapidly multiply by mitosis, there is an increased blood supply, the endothelial cells of the capillaries contract and allow the microphages and macrophages to escape, and these englobe the threatening bacteria and digest them. The microphages are the phagocytes that attack most bacteria, though some, such as tuberculosis, are digested by the macrophages. The macrophages are in the main the scavengers. They consume dead blood cells and the microphages which have been overcome in the struggle. The dead and living cells, the bacteria, the mucus, and the fibrin released from the cells compose the exudation. The crypts act as sewers or drains by which the exuded matter is removed from the body. It is quite probable that the lymph corpuscles of the tonsils furnish fixatives which are of the utmost importance in its defense against toxins. Delazenne of the Pasteur Institute has proved conclusively that enterokynase, the digestive fixative discovered by Pawlow, is a product of the Peyer's patches of the intestine, and we know how similar in structure Peyer's patches are to the tonsil. Chemotaxis must be considered. It is the name given to the phenomenon exhibited by certain cells of moving towards (positive) or moving away from (negative) certain other cells or substances. When negative chemotaxis occurs, the phagocytes refuse to be attracted to the bacteria. Just what causes this is not yet understood, but virulence has a great deal to do with it. If the virulence of the bacteria is very great, the phagocytes seem to give up without a struggle and allow infection to occur. This condition is often seen in infectious diseases. It has been explained by the theory that phagocytosis is a struggle for existence on the part of the cells, and not a means to accomplish an end, so the results are by no means perfect. If the leucocytes are unable to destroy the bacteria and they gain entrance into the body, or if enough of their toxins gets into the blood by absorption, we have the characteristic symptoms of the disease.

In considering the relation of the tonsil to infectious diseases, diphtheria is the most important disease to be considered. There is no better example of the phagocytic action in the tonsil than is shown in this disease. Cases have become so numerous in which the process of diphtheria has extended no further than to produce a lacunar tonsillitis that we have given them the name of bacteriological diphtheria, for a diagnosis would not have been made but for the finding of the Klebs-Löffler bacillus. Diphtheria also gives us an example of negative chemotaxis. In 1888 Roux and Yersin isolated the soluble toxin of diphtheria. If the bacteria are very virulent and this soluble poison is produced in large quantities, negative chemotaxis is produced and the phagocytes refuse to act. In diphtheria we have an example of the specific action of the bacteria. They produce necrosis of the epithelium, and the membrane, which is composed of a fibrous reticulum, in the meshes of which are found lymphatic cells, red blood corpuscles, and degenerated epithelium cells, becomes adherent. It is a fact that there is no adherence to the surface where the epithelium is intact. The action of antitoxin in conferring immunity opens a most interesting subject. That the antitoxin unites with the toxin in the blood to render it innocuous, as claimed by Erlich, is not incompatible with the theory of Metchnikoff that it stimulates the phagocytes to increased activity. In artificially acquired immunity the blood serum undoubtedly has antitoxic action, but Metchnikoff has conclusively proved it never has bactericidal action unless phagolysis occurs and the cytases are released from the phagocytes. The controversies between the biological and the chemical schools on the subject of immunity are far from being settled, but up to the present time Metchnikoff has most successfully defended his position. In scarlet fever we have many examples of phagocytic action in the tonsil. Children exposed to scarlet fever develop tonsillitis, and nurses and parents also have tonsillitis, but no scarlet fever. The relation between tonsillitis and rheumatism is of great importance. Rheumatism is so frequently preceded by tonsillitis that it seems to me to be a question if there is a specific germ for rheumatism. The soluble poisons or toxins of several different bacteria may, on account of faulty elimination, be deposited in the joint membranes and cause the arthritis. German observers have caused the symptoms of rheumatism in rabbits by inoculating them with the exudation of tonsillitis, but that does not prove that it is specific. Regarding rheumatism, Kiefer has pointed out an interesting fact in the treatment of tonsillitis. In a series of 120 cases 60 were treated in the ordinary way and 60 were treated by the local application of acetic salicylate. The first 60 were followed by 9 cases of articular rheumatism, while the second 60 were not followed by a single case of rheumatism. He observed 2,275 cases of tonsillitis. Of his cases of rheumatism 21.3 per cent. could be traced to a previous tonsillitis. The other infectious diseases in which lacunar tonsillitis, or, as it might be called, phagocytosis in the tonsil, occurs are numerous. I have often seen it in measles. It occurs in erysipelas, smallpox, plague, etc., but it will be necessary to discuss other examples to bring out the point of the paper. Phagocytosis occurs when any morbid agent excites a positive chemotaxis in the tonsil.

I have so far considered only the infections. Phagocytosis in the tonsil is also caused by inorganic and organic particles. Weavers, file-cutters, needle-grinders, and those working at similar trades, are especially liable to tonsillitis. Whether the inorganic and vegetable particles are the primary causes, or whether they injure the tissue and lay it open to infection, is a question. Wright, in a very interesting paper, has shown that colored dust passes into the interior of the tonsil when the microbes do not. He attributes this to a positive chemotaxis of the cells for the dust particles and a negative for the microbes. Dr. Wright does not use the word chemotaxis correctly, as I understand it. If there were a negative chemotaxis, as he says, the bacteria would be unopposed by the phagocytes and they would enter and set up systemic infection. As I look at it, there was, in the case he cited, no chemotaxis at all, but the microbes were not present in sufficient quantities or were not sufficiently virulent to attract the phagocytes or to overcome the

normal desquamation of the epithelium and the phagocytes that normally issue from the tonsil.

The function of the tonsil has been discussed by many authors and it has been assigned a rôle as insignificant as shaping the bolus of food. Most writers seem to consider its function in health of little moment and that it is of no importance except when diseased. The fact that the tonsil may be frequently diseased and by hypertrophy become a menace to the body, is not an argument against its acting in a defensive rôle. Defensive power lies primarily in the cells, especially those derived from the mesoderm. Cells often defend themselves at the expense of the tissue and organs, and organs and tissue at the expense of the body as a whole. Sclerosis is primarily an endeavor on the part of Nature to defend itself against irritants and often causes destruction of the body; for example, endarteritis and the various scleroses of the kidney, liver, etc. The phagocytes undoubtedly take part in the formation of connective tissue. They surely do in formation of granulation tissue. Metchnikoff has shown that the vascular loops in new tissue are projected by the phagocytic action of the endothelial cells of the vessel walls. It is quite probable that some of the phagocytes become connective-tissue cells.

The tonsil is frequently spoken of as a port of entry of infection, but we must not forget two facts: First, that a generalized infection may determine the appearance of a secondary tonsillitis, whatever may have been the port of entry of the infection. It is quite possible, and indeed must often happen, that the disease, whatever the port of entry, lowers the resistance of the tonsil, and allows the germs of that disease or other pathogenic germs to get a foothold. The second fact is that the systemic infection takes place either in spite of the lacunar tonsillitis, in which case the tonsil attempts to resist infection, but is overcome, or when negative chemotaxis occurs and the phagocytes give up without a struggle. It is very probable that the tonsil is more bactericidal in its defensive action than it is antitoxic. This would account for the large number of cases of rheumatism, muscular rheumatism, and albuminuria, as pointed out by Adler, which, I think, are due to the faulty elimination of soluble poisons; it would also account for the headache, pains in the back and limbs, and other systemic symptoms of poisoning in every case of tonsillitis.

I believe the tonsil is so well defended that it seldom is the port of entry, as claimed by so many authors. This would seem to be borne out by the fact that, although the crypts are always teeming with pathogenic bacteria, general systemic infection is comparatively rare. Furthermore, as Adler has pointed out, systemic infection is more apt to follow insignificant anginas and an extensive inflammatory reaction seems to prohibit general infection. The tonsil must be continually exposed to the germs of tuberculosis, yet primary tuberculosis of the tonsil is rare. In a certain proportion of sections of the tonsil we find tubercles, but this is only the evidence of the defensive action in localizing the disease. Metchnikoff, who has made an extensive study of tuberculous inflammation, has shown that the giant cells which assist in walling off the bacilli, are aggregations of macrophages which have coalesced. In diphtheria we seldom have a grave infection unless the membrane extends beyond the tonsil, which would show that the tonsil was at least better adapted to resist infection than the surrounding tissue.

Finally it is possible to have a chancre of the tonsil and a chancre of the lip five days later, which I think is convincing proof that there is a defensive action in the tonsil preventing the primary immunization of syphilis.

I have endeavored in this paper to show:

That the tonsil is anatomically admirably arranged to resist infection.

That it is continually exposed to the action of pathogenic germs.

That when we have an inflammation of the tonsil it is caused by a pathogenic germ which is endeavoring to enter, and the inflammation itself is essentially a defensive reaction.

That when the resistance of the body is lowered from any cause, or the germs are virulent enough to overcome the other means of defense, which the tonsil has in common with the rest of the oral mucous membranes, or if the tonsil is wounded, a positive chemotaxis having been produced, there is a lacunar tonsillitis.

That when a negative chemotaxis is produced, either on account of the virulence of the infection or from some other unknown cause, there is a general systemic infection without a tonsillitis.

That when we do have a systemic infection it is either in spite of the defensive reaction or on account of negative chemotaxis.

That finally the relation of the tonsil to infection and infectious diseases is one of protection, and the disease we call lacunar tonsillitis is an example of phagocytosis and is a defensive reaction.

A NEW STREPTOTHRIX PATHOGENIC FOR CATTLE.

(STREPTOTHRIX OF BOVINE PNEUMONIA.)

By MAJOR CHARLES F. KIEFFER,

SURGEON UNITED STATES ARMY, PORT D. A. RUSSELL, WYOMING; ON DETACHED SERVICE WITH ARMY OF CUBAN PACIFICATION AT SANTIAGO DE CUBA, CUBA.

THE morphology and classification of the streptothrices is still far from being settled. As a class they stand between the moulds and the bacilli, but the border line varieties are by no means sharply located. For instance, it seems almost necessary to class some stems of the *B. tuberculosis* as streptothrices.

It is, therefore, important that all facts bearing on the streptothrices, whether in man or animals, should be reported and sufficient data collected for a definite classification of these organisms.

Broadly speaking, the pathogenic streptothrices, both in man and animals, cause two classes of lesions. The first and most important are the granulomata, the pseudotuberculous, and the pseudomycotic lesions. Second, the inflammatory processes going on to abscess formation and frequently to pyemic states. A large proportion of the organisms are both acid and alcohol fast; some are not. The list of severe, and in large part fatal, cases in man is growing rapidly. Ashton and Norris have collected the clinical data of twenty-six cases. Mayer reports ten cases and I have seen, in my own practice, two cases. I am convinced that many more cases would be discovered if a laboratory technique more suitable for staining the organisms were employed. I believe it would be a good laboratory procedure in all examinations of sputa to make two series of studies of the specimens. In the first one, using the ordinary technique preferred by the individual worker for demonstrating *B. tuberculosis*. In the second, employ the same stain, but omit the acid decolorization. This procedure has been followed in my laboratory for some time and gives most interesting bases for comparison.

The present report concerns a hitherto undescribed streptothrix. The organism was demonstrated in and isolated from the organs of two cows. In a small herd of milch cattle, fourteen head, three cows sickened and died within the space of a week. Four days later a fourth cow became sick and was examined by veterinarians. Being unable to make a diagnosis they brought the organs to me for bacteriological examination. A few days later a fifth cow died after being noticeably sick only four days. The organs of this animal were also delivered to me.

A careful post-mortem examination of the first carcase was made by Veterinary Surgeon Sproule, Artillery Corps U. S. Army. The only epidemic cattle diseases observed in that vicinity during the year (1904) had been hemorrhagic septicemia and symptomatic anthrax. During the post-mortem examination particular search was made for evidence of the latter disease. For this reason the carcase was skinned, but no subcutaneous hemorrhages or nodules of any kind were found. The spleen was apparently normal. It was of the usual size and consistence, and there was no capsular inflammation or thickening. The liver was normal in appearance and size. Both lungs were markedly congested and contained numerous fairly large consolidated areas. These areas on section were found to be engorged with blood and exuded a grayish purulent fluid. The heart was considerably hypertrophied. The right auricle contained a finely laminated pinkish white and gray clot, the size and shape of a tennis ball. The center of the clot was broken down and extremely fetid. Dr. Sproule states that the clot was just as fetid when removed from the animal two hours after death.

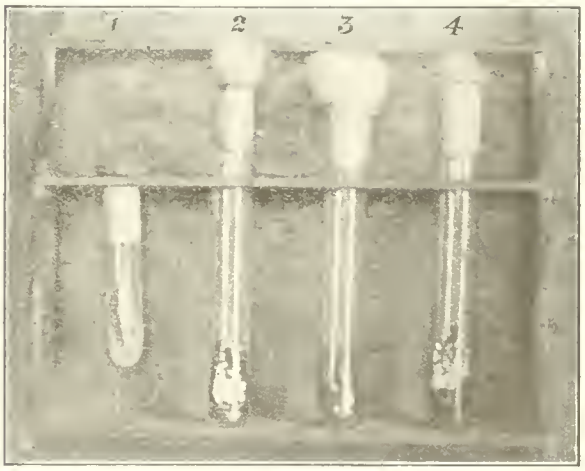

FIG. 1.—Culture of streptothrix: 1, blood serum; 2, glycerin-agar; 3, plain agar; 4, glucose agar.

FIG. 2.—Smear preparation from the lung of cow No. 5; showing beading, irregular staining and two cones; stain, carbol-fuchsin. × 1,100.

Smears made from the liver showed nothing. Smears from the consolidated areas in the lungs showed numerous streptothrix forms, which will be described later on. The same organism was observed in the broken down material from the auricular clot, combined with a short bacillus and numerous cocci.

Inoculations were made on agar, serum, and bouillon tubes from the lungs, heart, heart clot, liver, and spleen. The tubes inoculated from the heart and liver remained sterile. On all of the others a fine growth was observed in twenty-four hours. This growth was found to be the same streptothrix which had been observed in the smears from the organs. In the tubes inoculated from the spleen it was present in pure culture. In the tubes from the lung and heart there was a mixture with various cocci.

Three days later a fifth cow died after being noticeably sick three or four days. Post-mortem examination three hours after death by Dr. Sproule showed the following: There were no subcutaneous

hemorrhages or nodules. Both lungs were actively inflamed. They were filled with consolidated patches and there were numerous smaller areas of hemorrhage. The appearance coincided very closely to those seen in the lungs of the first cow examined, excepting that there was a much greater proportion of the lungs involved and there was also a greater degree of engorgement. The heart was enlarged to at least twice the usual size. The pericardium was much inflamed and thickened, the parietal layer being at least half an inch thick. The inner surface of the entire pericardial sack was covered with a thick, shaggy, grayish-yellow exudate. The sack contained six quarts of pus. This pus was greenish gray in color, peculiarly oily and greasy looking, and was extremely fetid. In it were found eight ounces of flabby yellow clot. On the visceral layer the exudate was not quite so thick as on the parietal layer; it was slightly adherent, but could be peeled off with little difficulty. The heart contained both white and red clots. The liver was slightly enlarged. The spleen was normal in size and texture. The kidneys were normal in appearance.

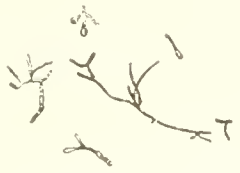

FIG. 3.—Streptothrix culture on nutrient agar, 10 days' old, stain, carbol-fuchsin. × 1,000.

Smears made from the lungs and pericardial exudate showed a streptothrix identical in appearance with that observed in the first case. Inoculations were made on agar, blood serum, and bouillon. A growth of the streptothrix was obtained from the lungs pure, from the spleen pure, and from the pericardium and pus mixed.

The herd was quarantined and a rigorous cleansing and disinfection of the stables and outhouses carried out. No further cases developed.

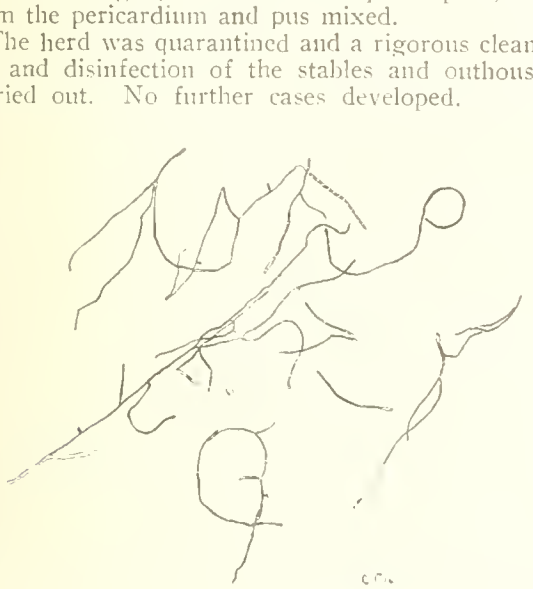

FIG. 4.—Streptothrix culture glycerin-agar, 24 hours old; stain, carbol-fuchsin. × 1,000.

The streptothrix grows on all of the ordinary culture media, but best of all on five per cent. glycerin-agar. On this medium the growth is very free. Numerous round, glue-like colonies develop, and in the course of 24 hours are about 1-32 inch in size. In 24 hours more the colonies grow very much larger and show a faint powdery white surface. In the next 24 hours the colonies become densely white and always show concentric rings. In the first 24 hours the appearance of the growth is like that of many of the ordinary pathogenic organisms and not at all like that of many streptothrix cultures. The colonies are lentil-shaped, tough and tenacious. They do not break up under the loop, but the whole colony comes bodily away from the culture medium. At the end of the first 24 hours a clear coffee-brown discoloration of the culture medium is observed around the colonies. This discoloration spreads and in a few days involves the bulk of the culture material. After two days the cultures give off a strong mouldy odor.

FIG. 5.—Streptothrix culture on nutrient agar, 24 hours old; stain Gram. × 1,000.

On neutral nutrient agar the organism presents the same cultural characteristics as on glycerin-agar, excepting that the growth is only about half as rapid. The same brownish discoloration of the medium occurs.

On glucose-agar the growth is about intermediate between the previous two. Otherwise the appearances are identical.

On blood serum small round colonies develop at the end of 24 hours. These colonies slowly increase in size and are surrounded by a zone of brown discoloration in the medium 1-8 inch wide. As the growth becomes older the colonies become grayish yellow and wrinkled.

On gelatin no satisfactory study of the growth was made, because the organism will not grow at all, or only with exceeding slowness, at any temperature in which the gelatin will remain solid. Transplantation of an entire colony is followed by a very slow increase in the size of the colony and scant formation of the brown stain without any evidence of liquefaction.

On potato the growth is very rapid. In 24 hours small gray colonies develop with faint discoloration. In 48 hours the growth is very copious, the colonies powdery gray and wrinkled, and the whole surface of the potato a deep, muddy chocolate color.

If a small colony is inoculated on bouillon in 24 hours, numerous minute colonies form without turbidity or any change in the medium. These colonies settle at the bottom of the tube, and when shaken up float in the liquid like small thistle downs settling very slowly to the bottom. In the next three days the colonies increase in size up to 3-16 inch. There is no discoloration or other change in the bouillon.

In litmus milk the blue color is discharged in 24 hours and in 48 hours the fluid becomes distinctly red.

The streptothrix does not form indol, nitrites, or gas.

On all of the media it grows at a temperature between 35° and 40° C., with its optimum at about 37° C. Above 40° C. the growth is very scant,

while no growth can be observed in transplanted colonies kept at the room temperature for two weeks.

It is aërobic. While growing freely on the surface of all the media, growth is exceedingly scanty in stabs below a depth of 1-4 inch. At a depth of 1-2 inch it will not grow at all. It shows no growth in anaërobic cultures nor in an atmosphere of hydrogen.

On all solid materials the organism seems to grow more freely on media of increased spissitude. Thus it will grow more freely on agar which has been prepared some weeks, so that slight shrinkage of the medium from the tube has taken place, than it will on the same medium freshly prepared.

In hanging drop there is neither motility nor molecular motion.

The streptothrix stains very freely with all of the ordinary aniline dyes. It is not acid fast. Decolorization is rapid and complete, with dilute mineral acids as well as with Gabbett's acid methylene blue. It is not decolorized by alcohol. It is brilliantly stained by Gram. Neisser's method shows no polar bodies. Special technique (Loeffler and Van Ermengem) fails to show any flagella.

In the original smears from the lungs a few cones were seen which seemed to be attached to the terminals of some of the branching filaments. I am not entirely satisfied as to the character of these bodies and not at all certain that they are part of the organism. The appearance of two of the most distinct cones is shown in Fig. 2. In old grown out cultures there were some appearances resembling these bodies. In such cultures the filaments were much shorter, with pronounced clubbing of their ends (Fig. 3). Fig. 4 gives a very good idea of the appearance of the organism grown on glycerin-agar. Most of the filaments are uniformly stained, but a few joints and branches are shown which have taken the stain very faintly. There is no tendency to form coccus-like chains, and little segmentation is observed in the branches. Fig. 5 shows the microscopical appearance of a culture of the same age as the preceding, on plain nutrient agar. It will be remembered that on this medium the growth was not so profuse as on glycerin-agar. In this form the tendency to the formation of coccus-like chains is quite marked.

Inoculation experiments were undertaken on all of the smaller laboratory animals, but with negative results. I sent some cultures of this organism to Professor Warthin for study. He informed me that inoculations in his laboratory on the smaller animals were also without result. I think it is quite likely that inoculations on the bovines might give a positive result, but I have had neither the opportunity nor facilities for developing any such research.

I have proposed to name this organism Streptothrix of Bovine Pneumonia (*Streptothrix pneumoniæ bovis*). A fairly complete working bibliography of the subject of pathogenic streptothricosis is appended.

THE PRESERVATION OF HEARING.*

By W. SOHIER BRYANT, A.M., M.D.,

NEW YORK.

The object of this paper is to call attention to the advantages of periodical aural examinations, and the benefits which would accrue to the patient through the easy correction of aural defects which, untreated, would later become serious or incurable, impairing the hearing and menacing the well-being, and perhaps even the sanity and life of the individual.

Otology can treat of no subject of more vital importance than the preservation of hearing, yet we never hear it mentioned. It comprises the whole field of otopathology, which it attacks with the most effective weapon, prophylaxis. The general practitioners, when they comprised the whole of the profession, with the exception of the eye and ear men, spoke slightingly of our specialty, perhaps because of their own unfortunate experiences in this field. They held that diseases of the ear were of two classes: First, those that would get well without treatment; and second, those that would not get well with any treatment. Since that time the surgical achievements of the otologist have rendered this ancient view ridiculous. Why, then, does there still linger deep in the minds of many outside of this specialty the opinion that the treatment of deafness is unsatisfactory, if nothing worse?

There is a very simple explanation of this feeling on the part of these benighted aliens. We must admit that most cases of chronic extreme deafness offer little encouragement for the restoration of perfect hearing. Such cases wrongfully detract from the fair fame and glory of otology. The otologist is expected to have a control over vital forces not even dreamed of by other practitioners. Why should he be expected to restore lost organs and tissues, or even to rejuvenate those which have undergone complete degenerative metamorphoses? Yet this is the fact in case of loss of hearing from suppurating ulceration or from calcification of the drum membrane and ankylosis of the ossicles. A general surgeon is not expected to restore a limb which has sloughed away, or an ophthalmologist to give sight to an eye darkened by neglected corneal ulcers. Why is the hearing mechanism so often allowed to suffer such vital losses? Is it not because nature has given man very many times the amount of perception of sound in normal hearing needed in dense civilized communities? A young person may lose 99 per cent. of his hearing before he is conscious of impairment. This deficiency may include the total loss of the hearing in one ear. He may, and in fact often does, allow a still further loss before he attempts to improve the condition.

A case in point came under my observation recently. A man, twenty-three years of age, came to me to be treated for a "running ear," which prevented his obtaining satisfactory life insurance. He was totally deaf in this ear and had in the other only 1-14400 of normal hearing, yet he claimed to suffer no inconvenience on account of deafness; in fact, did not consider himself deaf. The hearing distance of his good ear for a watch was four inches. The normal distance for this watch was forty feet at his age, making the index of his hearing 1-120, which when squared to show the amount of hearing gives 1-14400 or 69-10000 of one per cent., a rather small proportionate amount.

Why will an intelligent person allow the loss of such a large part of what is perhaps the most important of all the senses—hearing? It is because his attention is not called to the fact. Sound perception is largely quantitative. The diminution of sound perception may not be noted until a very large part has been lost. As long as the requisite quantity for ordinary use is preserved, the individual remains oblivious to the deterioration. The conditions are reversed in the eye where the perception is largely qualitative rather than quantitive. The volume of light is of little importance, whereas the definition or quality is everything. The least deterioration becomes apparent by indistinctness and blurring of objects. Defective ears require louder sound because the sound-conducting mechanism is clogged. Brighter lights are no advantage to defective eyes because the accommodation or translucent media are defective. Their refractive not their conductive properties are at fault.

The layman has not yet learned to practise the same economy of his ears as he does of his teeth, for example. He does not go at regular intervals to the otologist, as he would to the dentist, in order that commencing defects may be corrected before they become serious. Nor does he go to the otologist as he does to the ophthalmologist as soon as any deterioration has taken place. A slight deterioration in sight is immediately perceived, whereas, as we have previously stated, a great loss of hearing may be brought about entirely unbeknown to the individual.

This scheme of prophylaxis would apply to all ear diseases and defects not congenital, among them those originating in the pharynx, the nose, the tuba auditiva, external auditory meatus, the ear complications of general diseases, nervous conditions, and trauma. We thus include the stubborn forms of deafness due to chronic middle ear catarrh, absolute deafness of labyrinthine, or nervous origin, as well as those inflammations of the tympanomastoid region which threaten entire loss of hearing and even life itself. At greater length we may catalogue them as inflammations of the pharynx, obstructions, adenoids, and tonsils; inflammation of the nose and irregularities, hypertrophies, and obstructions; obstructions and inflammation of the tuba auditiva; inflammation of the middle ear and faulty nutrition and atrophy; deficiency in the nerve function of hearing, inflammation of the external canal, obstruction by foreign bodies, cerumen, etc., and new growths, and especially the common insidious disturbances of the acoustic balance.

Inflammations of the pharynx involving the nasopharynx, extend to the Eustachian tube and cause impairment of its functions, drainage, and ventilation. The slight chronic pharyngitis that is often found in mouth breathers, gouty or syphilitic people brings about insidious changes along the tube and middle ear. Gross obstructions to respiration, hypertrophied adenoids and tonsils, bring about the

*Read before the Harvard Medical Society of New York, December 22, 1906.

same conditions. Smaller ones may be large enough if conveniently placed to cover the mouth of the tubes or press against them. A very small amount of adenoid tissue in the fossæ of Rosenmuller can seriously impede the action of the tubes. Irregularities and impediments to the flow of air and the blood, and lymph circulation of the nasal fossæ can cause disturbances of the Eustachian tube and its connecting cavities.

The changes which affect the hearing most insidiously are of two kinds: those chiefly inflammatory, and those chiefly due to defective ventilation. The final results in either case are much the same. The inflammation first causes congestion and increase of the connective tissue elements, then contraction, anemia, faulty nutrition, atrophy, and degeneration. The choking of the Eustachian tube causes the same results without intervention of inflammation direct through the congestion and stagnation of blood and lymph. Defect in the manumetric balance of the tympanum directly affects the drum membrane. When there is negative pressure the membrane is sucked inwards flexing the ossicular chain. When there is increased pressure in the tympanum, the membrane is pushed outward, extending the ossicular chain. Either of these positions is detrimental to the best sound transmission, and when continued long the effect is lasting. Overextension has a detrimental effect on the elastic fibers of the membrane and the ligaments of the ossicular articulations, which yield in time to the overstretching. All these changes affect the acoustic balance directly, and render it less capable of transmiting the sonorous vibrations. This pathological cycle when once started tends to progress rather than cease spontaneously, and the structural alterations have no tendency to repair without surgical aid. The atrophy, when once well under way, goes through all the series of changes consequent to faulty nutrition, involves the drum and its contents, and even spreads to the labyrinth.

Decrease of sound perception is the most delicate measure of general nervous exhaustion. It may indicate the commencing of nervous changes which later will destroy the hearing or affect the nervous system very seriously. Inflammations of the external canal are often remarkable for the great amount of pain a comparatively trivial affection may cause. The drum membrane is sometimes affected. Occasionally the canal is entirely closed, cutting off the hearing. Foreign bodies and impacted cerumen act in much the same way. New growths sometimes close the canal and cut off hearing permanently, as well as threaten life when malignant. Some of the benign osteomata are easily controlled if they are observed in time. Impairment of the acoustic balance is especially prone to come on unobserved, whatever its causes, and the hearing is seriously affected before the patient notes any change. Clogging of the Eustachian tube is a long step on the road to deafness. It is also the chief determining factor in mastoiditis. When there is suppuration of the middle ear and an open Eustachian tube, convalescence takes place before the mastoid inflammation reaches any importance. When the tube is clogged, the suppuration is likely to persist in the mastoid antrum and cells.

Early observation will detect these insidious conditions, which cause over 95 per cent. of deafness, and judicious treatment cure them before serious impairment has taken place. We suggest that the otologist should be consulted once a year, after every cold, and when anything unfavorable is noticed in the ear, which is often the case in general nervous affections, exhaustion and general diseases, as well as when there are any alarming ear symptoms.

ACUTE EDEMA OF THE PHARYNX, WITH REPORT OF A CASE REQUIRING RAPID TRACHEOTOMY.

By GOETHE LINK, M.D.,

INDIANAPOLIS, IND.

ASSOCIATE PROFESSOR OF GENITOURINARY SURGERY IN THE STATE COLLEGE OF PHYSICIANS AND SURGEONS IN AFFILIATION WITH INDIANA UNIVERSITY.

In the following case while it could not be definitely established that there was no laryngeal edema the condition was primarily and essentially an affection of the pharynx. There is no anatomic reason why complete asphyxiation could not occur from an acute edema of the pharynx without any involvement of the larynx or its aperture. Semon and Williams in classifying acute septic inflammations of the pharynx give as one class "acute edematous tonsillitis, uvulitis, pharyngitis, epiglotiditis, arytenoiditis, and cellulitis of the neck." As these authors have pointed out, it is impossible to draw any definite line between the purely local and the more complicated cases or between the edematous and the suppurative forms, all being different stages or degrees of reaction to infection.

That the more severe symptoms of an edematous nature may be present without the severe suppuration following is shown in this case. No doubt it is to the benignity of the infection, the edematous stage being past, that the patient owes his life. Why

Hard rubber vaginal tip used, two-thirds exact size. At subsequent removal the end was cut smooth and polished. Sterilization by boiling before reintroduction has caused the tube to straighten from the original angle.

this should have been of such a severe character at one time and later so mild is hard to understand.

At twelve o'clock at night I was called to see a patient whom I had never treated before, and, being told that he was choking to death, went prepared to deal with an attack of asthma. Upon my arrival in the sick room I found the patient sitting in a chair with much cyanosis, tongue protruding, saliva escaping, and laboring at each breath. Patient was a man weighing 250 pounds, having a very large neck, and an accumulation of fat constituting a double chin. His history was hurriedly given me as follows: One hour before my arrival his throat had been lanced for the eleventh time in the course of a tonsillitis with which he had been suffering for ten days. Thinking I had to deal with a post pharyngeal abscess, I quickly introduced my finger into the pharynx. To my surprise I found the structure so swollen and the opening so tight as to make the introduction of my finger difficult. On the left side was a wound in which I could easily bury a finger. This I cleansed of blood and mucus. Noting the very feeble pulse I gave hypodermatically 1-30 gr. of strychnine sulphate. I then emptied into the patient's throat one-half dram of suprarenalin, all that I had with me, and dispatched the only other man in the house to the nearest drug store for more. Thinking I might intubate past the swollen pharynx, I asked for a tube of some kind and finally a vaginal tip to a hard rubber syringe was handed me. This was elbowed almost at a right angle.

I soon found it impossible to intubate, as anything long enough to reach the larynx, in the swollen condition of the soft palate, could not be turned in the space present. The syringe tip was laid aside after a few attempts. The patient's neck was surrounded with cloths wrung out of ice water. To my surprise the breathing became more difficult. While I was preparing a local anesthetic in order to do a tracheotomy, the patient ceased to breathe and became unconscious, making an anesthetic unnecessary.

All had fled but one woman, and while she kept his head from falling in my way I performed a low tracheotomy, fearing to enter higher on account of the edema, the extent of which I did not know. As the only light was that afforded by an overhead gas jet, the operation was for the most part done by the sense of touch. Kneeling in front of the patient, who was in a sitting posture, I incised the skin and deep fascia in the median line two inches above the sternal notch. Introducing my finger I worked my way bluntly to the trachea. Feeling the tracheal rings I introduced my knife, edge upward, along my finger. The trachea was then stabbed and cut slightly upward. The knife being withdrawn a closed hemostat was introduced to the trachea, was opened, and was pulled out after the manner of treating an abscess. This enlarged the wound sufficiently for the introduction of a tube. This method, while not elegant, was sure and safe. The intense carotid pulsations on both sides of the guiding finger served as a warning that blunt dissection was to be preferred to cutting. Very little blood was lost.

Sticking a silver female catheter, which I found in my pocket case, into the wound, while my woman assistant held it in place, I performed artificial respiration. After some time we were rewarded by a deep inspiration. This, however, was followed by a convulsion which made it a very precarious matter to have such a small instrument in the wound, the neck being so thick that only a short bit was protruding for a hold. Casting about for something else to use in the wound, I took the hard rubber vaginal syringe tip with which I had tried to intubate and quickly whittling the end inserted it. The elbowed shape fitted perfectly and left enough for the threaded end to be tied securely with tape. In one-half hour the patient asked to be put to bed; and, breathing entirely through the tube, soon slept the first sleep for several nights.

The patient progressed to an uninterrupted recovery. No sloughing nor suppuration occurred except some pus, which came from the surface of the incisions. These had evidently been made into a solid tonsil and later infected. Urine examination next day showed nothing abnormal.

The previous history of this case is interesting as leading up to a condition so nearly fatal. He had suffered with a simple tonsillitis ten days. Three or four days previous to my visit the family physician incised the left tonsil and repeated this at each visit until the last incision was the eleventh. At no time did any escape of pus follow the incision. Hydrogen peroxide and a proprietary antiseptic wash had been used with the salicylates internally. In the emergency coal oil had been swallowed to relieve the edema until the patient could not swallow. While the nature of the emergency prevented a thorough examination, fortunately attempts to relieve the edema gave all the information that could be gleaned from palpation. Upon introducing my fingers into the throat four distinct points of pressure could be felt. These seemed to be bulgings of the anterior, lateral, and posterior walls. The latter especially felt like the half of an orange. This swelling increased rapidly in the few minutes that I made several examinations, until finally there was complete occlusion and my fingers were introduced only with great effort.

The edema declined as rapidly as it had arisen, so that within three hours the patient could talk, when the tube was closed and air forced through the natural channels. No suppuration followed, and one month later I removed both tonsils. They were imbedded so as to be almost entirely hidden by the pillars. Carefully dissecting them out, there was very little bleeding. The tonsils were hard and fibrous and honeycombed with crypts. No edema followed this operation and the patient's throat is now clear of all tonsillar tissue.

BRIEF REPORT OF A CASE OF TRICHINIASIS.*

By José M. Ferrer, M.D.,

New York,

Visiting Physician to the St. Vincent's and the French Hospitals.

A. D'E., an Italian peddler, twenty-nine years old, was admitted to my service in St. Vincent's Hospital on November 9, 1906. He had been ill a week with fever, headache, marked prostration, diarrhea, occasional chilly feelings, slight cough, and persistent muscular pains in the arms and legs. He had had a nosebleed in the early part of the week.

On admission he looked very ill, was perspiring freely, and coughed a little. His temperature was 102°, pulse 84, and respirations 24. The tongue was coated and quite red at the edges; spleen was distinctly palpable. There was no eruption and the abdomen was not distended. There was slight bronchitis. His heart, lungs, and liver seemed normal. There was nothing unusual in his throat. The urine was not scanty. It showed a marked diazo reaction; was dark amber, alkaline, of a specific gravity of 1.028, showed no albumin nor sugar, and contained numerous triple phosphate crystals.

A tentative diagnosis of typhoid fever was made and the case was manged accordingly.

During the next week the patient was very ill; dull and apathetic, with a temperature range of 103° to 105°, slight diarrhea, marked headache, profuse sweats, and pains in the limbs and occasionally in the abdomen. The course of the disease seemed, however, unusual for a typhoid. It was observed that the temperature, while it rose to 104° and 105° in the evening, would drop next morning to 100½° or 101°, a difference of three or four degrees for the second week of typhoid. There was no delirium. There was no sordes nor herpes on the mouth. There was absolutely no distention of the abdomen. No eruption appeared. There were no characteristic fecal movements. The blood was examined on three different days and the Widal reaction (1 to 20) was negative. The white count was high, on four different days being 17,000, 18,000, 16,000, and 14,000.

Thinking that the up and down temperature, the bronchitis, the diazo reaction, the pains, etc., might be due to miliary tuberculosis, the sputum was examined on four different days and the blood was also examined, but no tubercle bacilli were found.

*Read at a meeting of the Society of the Alumni of City (Charity) Hospital on December 12, 1906.

As the man had an enlarged spleen, occasional chilly feelings, up and down temperature of high range, marked headache, and profuse sweats, it was thought that there might be a malarial infection. Examinations of the blood for parasites were made on three different days, but none were found. He was given thirty grains of quinine a day for four or five days, but it seemed to have no beneficial effect on the disease, and it was stopped. The profuse perspiration continuing and being unaffected by atropine sulphate and acid sponging, it was thought that the quinine might be producing it, but when this drug was stopped the sweats continued.

On the eighteenth day of the disease the temperature dropped to 99° and remained fairly low. The diarrhea had ceased. His general condition improved markedly. With what had gone before, the diagnosis of typhoid was no longer tenable, and he was allowed to eat, without bad results.

The pain and tenderness in the arms and legs, however, continued, and seemed to be in the muscles and not the neuralgic pains of typhoid fever. Emaciation was pronounced. The white blood count remained high. In the last few years we have had in the hospital three cases of trichiniasis which acted in a similar way, and I suggested examining the blood for eosinophilia as a possible aid in diagnosis. On four different days the blood showed marked eosinophilia. The differential white count on November 10 showed the following percentages: Polynuclears, 69; large lymphocites, 12; small lymphocytes, 4; eosinophiles, 15; no myelocytes, no mast cells. On November 28 the differential count showed: Polynuclears, 71; large lymphocytes, 4; small lymphocytes, 10.5; eosinophiles, 8.5; no myelocytes, no mast cells. The patient declared that he was very fond of pork, often partook of it in many forms, and had eaten some the very day he fell ill. An incision was made over the right shoulder and a small piece was removed from the deltoid muscle and examined carefully. The trichinæ were found in moderate number.

The patient continued to improve and was up and about the ward on November 20, a little over three weeks from the beginning of his disease.

441 Park Avenue

The Application of Galvanism to the Treatment of Fibroids.—Franklin H. Martin thinks that electricity may be used with benefit in a small percentage of cases of fibroids of the uterus. He says that electricity is especially indicated in small bleeding fibroids in women approaching the menopause; in inoperable cases; in incipient, uncomplicated fibroids in women over forty years of age; in small, uncomplicated fibroids of the smooth, interstitial variety which have no symptoms but hemorrhage; in cases not accompanied by pelvic pus accumulation in which the patients persistently refuse to have an operation. In his treatment of typical cases the writer passes a large copper electrode of suitable shape and diameter to the bottom of the uterine canal. The vaginal part is insulated with a rubber muff and this electrode is then attached to the positive terminal of the battery. The other electrode is placed on the abdomen and is then attached to the negative pole of the battery. As a rule the patient may safely be given as strong a current as she can bear without danger of producing excessive cauterization at the active pole. This varies from one hundred to two hundred milliamperes. The duration of each treatment should be five minutes for the maximum current employed. The treatment should be given as often as every second day. In cases in which an intrauterine electrode is not practical some other form of internal electrode should be used which will have the effect of causing the current of galvanism to pass directly through the largest part of the tumor. The writer declares that some of his most gratifying results have been obtained in cases of the apparently hopeless variety.—*The Archives of Physiological Therapy.*

The Roentgen Treatment of Hodgkin's Disease, Leukemia, and Polycythemia.—Henry K. Pancoast declares that although conservative men are beginning to look upon the Roentgen specialist as overenthusiastic in his claims, and perhaps with some justice, nevertheless, at the same time, these very men stand willing to acknowledge that the *x*-ray has great value and is the most reliable agent in treating leukemia. Tissue destruction is doubtless the greatest factor in the results accomplished in the *x*-ray treatment of leukemia. In the case of a leukemic patient, the toxic conditions should be carefully studied and the tissue destruction should be investigated before and after beginning *x*-ray treatment. Dangerous effects should be guarded against. Each case of this kind should be reported in detail. The writer refers to a case of Hodgkin's disease in which all of the superficial lymphatic glands and the spleen were markedly enlarged. Under prolonged *x*-ray treatment these were very much reduced in size but whenever the exposures are discontinued for any length of time there is always a tendency for the recurrence of the manifestations. In the case of polycythemia there seems to be as yet no tendency toward a permanent reduction of the number of red cells to normal.—*The Archives of Physiological Therapy.*

The Importance of a Microscopical Examination of All Growths Removed from the Nares, Together with a Report of Early Diagnoses of Malignant Growths.—Sylvan Rosenheim calls attention to the great importance of early diagnosis in a case of malignant growth. In no class of cases is the lack of such diagnosis so serious and so sure to lead to evil results. When such cases finally come to the general surgeon they are either inoperable or do not recover after operation. If all growths from the nose are systematically examined, they will be correctly diagnosed while they are still small, and they may, as a rule, be easily extirpated by the nasal route. When this route is not feasible the radical operation can be done at a time when there is the greatest probability of a cure. The physician will then be on the watch for recurrences and will be in a position to treat them vigorously. The writer then cites the history of a number of cases in point. In Watson's series of one hundred and fifty cases of sarcoma of the nasal passages there was a previous history of polypi in sixteen per cent. In Bloodgood's series of cases of carcinoma of the antrum there was a history of polypi in nine of them, which arose from the nasal fossæ, lasting from one to twelve years.—*Bulletin of the Johns Hopkins Hospital,* June, 1906.

Concerning Local Anesthesia and Sensitiveness of the Organs and Tissues.—K. G. Lennander calls attention to the four methods of contact, pain, pressure, heat, and cold, to which the skin reacts. Underneath the skin lie the muscles and aponeuroses with a sensitiveness relatively slightly developed. Underneath these tissues are the serous membranes, the periosteum and the synovial membranes. The parietal pleura, the parietal peritoneum, and the adjacent subserous tissues, the periosteum and the synovial serous membrane are all sensitive to pain. On the contrary, the writer believes that they are not susceptible to the other three tactile methods of pressure, heat, and cold. As far as he has been able to ascertain, the bones, cartilages, the brain, the lungs, the heart, and the blood-vessels, after they have been separated from the connective tissues about them, the thyroid gland, the liver, the spleen, the pancreas, the renal parenchyma, the internal female genital organs, and those parts of the testicle which are covered with serous membrane, do not react to any of these methods of contact, according to all appearances. He believes that this is absolutely demonstrated at least for the stomach, the intestinal tract, and the gall-bladder.—*Gazette des Hôpitaux Civils et Militaires.*

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

THOMAS L. STEDMAN, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51 FIFTH AVENUE.

New York, March 2, 1907.

THE NEW YORK MEDICAL BILL.

It is reported that the homeopathic and eclectic physicians of this State are strongly opposed to the bill now before the legislature for the unification of the medical examining boards. Why this should be so we cannot imagine, except upon an assumption which would be far from complimentary to our brethren in the other schools of practice. The bill provides for a single board, before which all who aspire to the right to practise the healing art must appear and pass a common examination on all the branches of medicine except materia medica and practice. As members of the eclectic and homeopathic State medical societies are to be represented on this board, and as the subjects of examination will be those only on which all educated physicians must be grounded in order to understand the nature of disease and to be able to recognize its presence in the individual, there would seem to be no valid objection on the part of our separated brethren to the plan. No questions will be asked regarding the treatment of disease, and the successful candidate will be at liberty then, as he is now, to prescribe drugs or manipulations, water or hot air, as may appear to him most appropriate.

It has been suggested that the opposition is due to the fact that the examinations of the homeopathic and eclectic boards are more lax than those of the appointees of the Medical Society of the State of New York, and that the graduates of the homeopathic and eclectic schools would be unable to pass the examination as now conducted by the appointees of the State Society. We do not think this can be so, and if it were the adversaries of the single board would hardly allege it as a reason for their opposition to the bill now before the legislature. There is, therefore, no valid excuse for their adverse position, and there are many reasons why they should favor the bill. In the first place a common examination would place all the members of all the schools of practice on an equal footing. It could not be said, as it is now said, rightly or wrongly, that the licensees of the regular board are better educated than those of the other boards, for all would then be subjected to the same test.

If there is but one board for the licensing of all practitioners, whatever their therapeutic principles may be, a bar will be placed to the admission to our ranks of uneducated men who know nothing and care nothing about anatomy, physiology, or pathology, but seek only for the legalization of the peculiar system of therapeutics which they profess to follow. If the three-board system is preserved it is only a question of time when it will be a four-board, a six-board, or a ten-board system. There will be the regular board—we use the term "regular" as a synonym for the incorrect word "allopathic," and disclaim any arrogance in the assumption of the title—the homeopathic board, the eclectic board, the osteopathic board, the naturopathic board, the mechanicotherapeutic board, the optometry board, the christian science board, and heaven knows what board, and the whole system of medical licensure in this State will be reduced to an absurdity. If there is a single board for examination on all branches of medical science, except materia medica and therapeutics, those who seek recognition for their peculiar tenets will have equal rights with all other practitioners. They have only to give proof that they are grounded in the essentials of medical science and then they can treat disease by drugs, by vibration, by replacing dislocated bones and tendons, by fitting glasses, by denying the existence of disease, or by taking the fee and doing nothing—and will all be equally liable to suits for malpractice if they mistreat their patients. All men will then be born equal in medicine and the race will be to the swiftest and to the one who is the most skilful in the treatment of disease and the alleviation of suffering. Nothing could be fairer than this. There will be then no monopoly in the art of healing and the door of medical practice will be open to every man or woman who has the educational key.

The single board bill in the Senate is No. 154, that in the Assembly is No. 160, and we would urge all our readers of whatever school of practice, who love their profession and long for its unification, to write to their representatives in both Senate and Assembly begging them to vote for this most commendable measure.

A SUBSTITUTE FOR THE CATGUT LIGATURE.

It has been said that the treatment of hemorrhage is the foundation of all surgery, and this requirement has been most fully met by one of Lister's greatest inventions, the absorbable catgut ligature. The material so successfully used in arresting hemorrhage by ligation of the bleeding vessels has served an equally important purpose in enabling the surgeon to unite structures severed by operation or accident by the employment of the absorbable buried suture. Catgut was used as a ligature and suture material before Lister's time, but it was his mode of rendering the gut sterile which permitted results to be attained never before possible. The early methods of sterilizing catgut possessed many drawbacks, but now by a gradual process there has been evolved a series of procedures which render the material practically sterile without impairing its tensile strength. The term sterile must be used advisedly, however, as localized infections may follow the use of catgut ligatures even under the strictest precautions. This led to the abandonment of catgut and a return for a time to the use of silk for these purposes. This always constitutes a foreign body in the tissues, the presence of which is

often resented, sometimes months and years after its introduction. Metallic sutures, silkworm gut, horsehair, etc., may all be included in the same class, for they all have the same disadvantages as buried sutures. Senn, in a recent article in *Surgery, Gynecology, and Obstetrics*, for December, 1906, refers to the ideal suture material as an animal tissue which can be made sterile by some effective means, which will not only destroy the existing bacteria, but will also neutralize the toxins which may have been generated in the dead tissue. A material of this kind must also possess the necessary tensile strength to meet the mechanical indications for a certain length of time, until the processes of repair have rendered its presence superfluous.

Catgut by no means fulfils all these indications, and yet it has held the field against substitutes which have been introduced successively during the course of many years. The source of the material and its preparation offer many opportunities for error which are familiar to every surgeon. Among the substitutes which have been suggested are the compact nonelastic tendons of some of the larger land and sea animals. Of these, kangaroo tendon, championed for many years by Dr. Marcy of Boston, has been the most widely used, and with general satisfaction. It may be thoroughly sterilized, but if used extensively the supply would soon give out. Dr. Senn in his paper suggests the use of tendons secured from some of the larger Arctic mammalia, which he has employed with good success. Material was procured from the whale, the narwhal, the walrus, and the seal, and after being dried and stripped it was treated with iodine in the usual manner. The results from the employment of these materials as buried sutures were excellent, and Senn was impressed to such a degree that he considers it superior to the tissue of all land animals, from both the anatomical and the bacteriological standpoints. It is apparently not so difficult to procure as would at first appear, for the natives of these regions use it constantly for their own purposes. If it can be made commercially available it is possible that it may be found to be an efficient substitute for catgut, which is quite generally acknowledged to be far from ideal.

GASTRIC ULCER IN CHILDREN.

A STUDY of post-mortem statistics shows that gastric ulcer is relatively uncommon in children, as compared with its frequency in adults, yet it appears to exist more often than is recognized by clinical examination. Hemorrhagic erosions, follicular ulceration, tuberculous and simple ulcers have all been demonstrated in children, but the symptomatology is very defective, as the greater number of cases have been demonstrated only accidentally at autopsy. Adler, writing in the *American Journal of the Medical Sciences* for January, 1907, has collected the available literature and subjected the same to analysis in addition to reporting a case which came under his own observation. Pain and tenderness were not often noted in the acute cases, but were present in most of the chronic cases. The pain was not severe, and was usually localized in the epigastrium. It was always paroxysmal, came on after meals as a general rule, and was relieved by vomiting. Hematemesis was noted in 40 per cent. of the cases in which histories were obtained, and in some cases was the immediate cause of death. Symptoms of indigestion were rarely noted, and then only in the chronic cases. Diarrhea was a prominent symptom, being present in almost one-half of the acute cases. A striking feature of acute ulcer in children is the large percentage of perforations, the symptoms of which are sharp, sudden pain in the abdomen, vomiting, and collapse, with death occurring in thirty-six hours.

The possibility of the presence of this condition should lead to the exercise of great care in the diagnosis of obscure gastrointestinal symptoms in infants and young children. The finding of blood in the stools and vomitus is probably the most certain means, but here care must be taken to eliminate all the other causes of hematemesis and melena, for these may be found associated in children with any one of a number of disease processes. With the advances which have been made in the recognition of occult hemorrhages, ulcer of the stomach in children will probably be more frequently recognized at an early stage in the disease when the application of curative measures may still prove of value. At any rate, in children suffering from chronic stomach disorders the possibility that their disease may be gastric ulcer should always be borne in mind.

THE TREATMENT OF BENIGN TUMORS OF THE BLADDER.

REFINED methods of diagnosis in diseases of the bladder, particularly the development of cystoscopy by Nitze and others, have demonstrated that the number of nonmalignant vesical growths is much larger than was formerly believed to be the case. The older statistics have shown that apparently only 0.30 per cent. of all bladder tumors were benign, whereas Nitze found that among 399 vesical tumors examined by him 177 (or 44.3 per cent.) afforded no evidences whatever of malignancy. This diagnostic conclusion seems supported by the result of the therapeutic procedures evolved in accordance with these findings. Nitze has developed the intravesical operation in order to meet the conditions presented by pediculated, benign tumors, not too extensive in size, and as a substitute for suprapubic cystotomy. His statistics, as shown in a recent paper by Weinreich in the *Archiv für klinische Chirurgie*, Vol. 80, No. 4, disclose that among 101 cases treated in this manner, a cure was effected in 70, and in only 18 did recurrences take place. Of course these patients were operated upon soon after the first symptoms were noted, and the growths were usually small, but the results show the feasibility of an operation which can be carried out with much less trouble and annoyance than suprapubic section, and gives equally good results.

It is generally assumed that the greater proportion of these benign tumors of the bladder soon become malignant, and for this reason regular cystoscopic examinations after the operation are indicated. As regards the possibility of postoperative hemorrhage, experience with this series of cases has shown that the danger is exaggerated, and that

it is not necessary to tamponade through a cystotomy wound in order to control the bleeding, as claimed by Cathelin. The intravesical method developed by Nitze will by no means entirely supplant the suprapubic route, but with the proper indications present it seems rational to employ it before resorting to the more radical procedure. It is self-evident that it can be done, however, only by a specially qualified operator, and this seems to constitute the sole drawback to its general adoption for the purposes indicated.

The Effect of Quinine on the Uterine Contraction.

Differences of opinion have long existed among obstetricians in regard to the value of quinine as an oxytocic, and while some observers have lauded it as a useful uterine stimulant others have considered it either of no value for this purpose or at best unreliable in its action. A comprehensive summary of these conflicting views is presented in the *Deutsche medizinische Wochenschrift*, January 31, 1907, by Mäurer, who also reports his own experiences with the drug. He administered it in sixty-three cases during labor and fifteen times in the treatment of abortion. In 78.2 per cent. of the cases he considers that an effect was produced which was the result of the medication and in the remaining 21.8 per cent. it appeared to be without efficacy. His experience leads Mäurer to believe that quinine undoubtedly strengthens the uterine contractions and perhaps may induce their onset, but that it shares with other oxytocics the disadvantages that its effects cannot be guaranteed in every case. According to Mäurer's experience its administration is not attended by any untoward action on either the mother or child, and the uterine contractions evoked are physiological in character. In explaining its mode of action he assumes that, granted a normal uterine musculature, in cases of inadequate contractions there is a lessened susceptibility of the muscle to stimuli and the quinine serves to increase the irritability of the organ to the nervous impulses in question. It was found that the nature of the quinine preparation is of no importance and that it may be given either by mouth or hypodermatically. Mäurer's routine method is to give one gram of the sulphate by mouth and if no effect is manifest at the expiration of an hour to give 0.5 gram more. If there is still no improvement in the conditions this dose is repeated in half an hour, but if this is ineffectual the patient is regarded as having an idiosyncrasy that renders her insusceptible to the influence of the quinine.

Heredity in Gastric Ulcer.

The ingenuity of theorists and experimenters has been so severely taxed in endeavoring to furnish a satisfactory explanation of the etiology and manner of formation of the so-called peptic ulcer of the stomach that it is a little remarkable that more efforts have not been made to introduce the element of heredity into the question. In a recent communication in the *Münchener medizinische Wochenschrift*, January 29, 1907, attention is drawn to this factor by Huber, who gives brief résumés of thirty cases in support of his opinion that a hereditary predisposition to the affection frequently exists. His own cases are eleven in number and form about fifteen per cent. of all the patients with ulcer of the stomach treated by him since January, 1905. The other nineteen histories were furnished by Bernhard, who believes that the element of heredity was present in about a third of the cases seen by him in the course of a long series of years. While some of the cases quoted by these authors can hardly be regarded as affording particularly good evidence in support of their views, in others the occurrence of the same affection in numerous closely related persons seems to be the result of rather more than mere coincidence. Huber dos not attempt to draw direct conclusions from the statistics he has collected, but offers the suggestion that possibly the explanation of the mode of origin of the affection is to be found in an inherited disorder of the innervation of the stomach, involving particularly the trophic impulses and in this way through the agency of some immediate exciting cause giving rise to the ulcerative process. In further support of his views he points out the much greater frequency of gastric ulcer in some regions, such as in the Engadine and in Thuringia, but it must be admitted that this is a pretty weak argument, for many other predisposing causes besides inbreeding may be active in circumscribed geographical districts.

Physiological Salt Solution as an Irrigating Fluid.

More doubt is being cast from day to day on the actual value of antiseptic solutions for purposes of irrigation in external wounds or in lesions of the accessible internal organs. The rational procedure would appear to consist in the use of a nonirritating fluid, the effect of which would be largely mechanical. These qualities are well met by the ordinary physiological salt solution, but in the desire to gain an antiseptic action, which has been greatly furthered by the numberless remedies of this character which have been placed on the market, this has been almost entirely forgotten. Pasteau (quoted in the *Medico-technologisches Journal*, 1907, No. 1) makes a plea for the use of the decinormal salt solution, particularly in genitourinary surgery, and considers that its advantages are sufficient to commend it as superior to all the other drug solutions. Among these are its absolute blandness and lack of irritating effect on the mucous membranes, which is present with the use of even the most dilute solutions of other materials ordinarily employed for this purpose. In using salt solution for bladder irrigation, it also has the advantage of dissolving blood clots and accumulations of pus, and thus facilitating their removal, whereas the action of most antiseptics is one of coagulation. Another point in its favor is that when some of the solution is left in the cavity irrigated, whether accidentally or by design, its absorption will have no deleterious effect on the organism. The case with which the solution may be prepared is another great point in its favor, as it is not essential to employ an absolutely sterile solution, for if used soon after being subjected to a half-hour's boiling, it fulfils all practical requirements.

Human and Animal Tuberculosis.

Few reports have evoked greater interest than that of the Royal Commission on Tuberculosis which receives lengthy editorial comment in a recent issue of the *Lancet*, February 9, 1907. The commission has found that "marked differences are met with between bovine tuberculosis and certain strains of

human tuberculosis in respect of their infective ability to certain lower animals (in particular to calves); but practically speaking the difference, where it exists, is always in one direction; whatever the animal in question the tubercle of bovine origin has the greater virulence. The experiments have extended to anthropoid apes which have been found readily susceptible to bovine infection. No reason has been shown for inferring that man alone possesses a specially lessened susceptibility to tuberculosis of bovine origin." The writer in the *Lancet* further says that "we are forced to conclude that it is more than ever necessary to take active steps to minimize the risk which the public runs from tuberculous food and tuberculous milk. We cannot be content to tell the public to boil or sterilize all its milk. We know from experience the limited utility of such advice. We want milk free from tuberculous infection as its source." This want, like many other human desires, is at present somewhat difficult of realization. What we want, and can get, is milk free from tuberculous infection—at its source if possible, but before it is delivered to the consumer at all events. The finding of the Royal Commission on Tuberculosis emphasizes the danger of tuberculous milk and the necessity of pasteurization of all milk derived from suspicious sources.

The Efficiency of Digitalis Preparations.

Although digitalis is one of our most valuable and widely used drugs, its administration is accompanied by so many uncertainties that it has fallen greatly in medical estimation and substitutes and derivatives without number have been brought forward to take the place of the older preparations. Efforts have at the same time been made to determine the reason for the uncertain and irregular action of the drug which is so often noted. Lowy, a well known Austrian pharmacologist, studied the effects of the infusion on frogs by injecting the same into the lymph sacs of the legs and then determining the time at which systolic contractions ceased (*Wiener klinische Wochenschrift*, No. 39, 1906). In order to study the influence of the constituents of the gastric juice on the efficiency of the infusion, pepsin and hydrochloric acid were added to the latter. It was shown that the strength of the infusion distinctly declined when hydrochloric acid was added in the proportion found in the gastric secretions, while the effect of pepsin was comparatively unimportant. A solution of strophanthus on the other hand was not at all affected by even stronger solutions of the acid. It was also found that at the ordinary room temperatures an infusion of digitalis lost about half of its original efficiency within twenty-four hours. This is apparently due to the presence of an organic acid which is developed during this time, and it may in most cases be inhibited by neutralizing the fluid. This record simply furnishes another instance of the necessity of preparing infusions of digitalis fresh for every prescription and points also to the need of an addition of soda solution in order to neutralize the infusison and prevent, if possible, the changes already alluded to. In general it is better to use the active principle of a drug, when it can be obtained in stable form and in definite strength, but in the case of digitalis many practitioners believe an effect can be obtained from the use of an infusion of the entire drug which it is impossible to produce with digitalin or others of the active principle preparations. Lowy's discovery of the cause and remedy for the determination of the infusion promises, therefore, to be of value in cardiac therapeutics.

Relation of Birth Rate to Population.

In a recently published report on British vital statistics, the Registrar-General, Sir William Dunbar, expresses the opinion that moderate birth rates, associated with low mortality among children, may be more effective toward keeping up the population than high rates associated with high mortality. He asserts that a high birth rate does not necessarily involve a larger effective addition to the population than does an average or even a low birth rate. In too many cases high birth rates are associated with excessive sickness and mortality during the first few years of life, the result being that fewer than the normal proportion of children survive for five years, while those who do survive have fallen below the normal standard of physical fitness. The statistics gathered have led to the conclusion that during the past thirty-five years about seventeen per cent. of the decline in the birth rate was due to a decrease in the proportion of young married women. About ten per cent. was due to a decrease in illegitimacy, while regarding the remaining seventy-five per cent. of the decrease, although a proportion was due to reduced fertility, ascribable to changes in the age and constitution of married women, there is little doubt that the great part was due to deliberate purpose.

News of the Week.

Army Medical Corps Examinations.—Preliminary examinations for appointment of assistant surgeons in the army will be held on April 29 and July 29, 1907, at points to be hereafter designated. Permission to appear for examination can be obtained upon application to the Surgeon-General, U. S. Army, Washington, D. C., from whom full information concerning the examination can be procured. The essential requirements to securing an invitation are that the applicant shall be a citizen of the United States, shall be between twenty-two and thirty years of age, a graduate of a medical school legally authorized to confer the degree of doctor of medicine, shall be of good moral character and habits, and shall have had at least one year's hospital training or its equivalent in practice. The examinations will be held concurrently throughout the country at points where boards can be convened. Due consideration will be given to the localities from which applications are received, in order to lessen the traveling expenses of applicants as much as possible. In order to perfect all necessary arrangements for the examination of April 29, applications must be complete and in possession of the Surgeon-General on or before April 1. Early attention is therefore enjoined upon all intending applicants. There are at present twenty-five vacancies in the medical corps of the army.

Examinations for Positions in the Marine Hospital Service.—The Bureau of Public Health and Marine Hospital Service announces that a board of officers will be convened to meet at the Bureau of Public Health and Marine Hospital Service, 3 B street S. E., Washington, D. C., Monday, April 15, 1907, at 10 o'clock A.M., for the purpose of examining candidates for admission to the grade of assistant surgeon in the Public Health and Marine Hospital Service. Candidates must be between twenty-two and thirty years of age, graduates of

a reputable medical college, and must furnish testimonials from responsible persons as to their professional and moral character. The examinations are chiefly in writing, and begin with a short autobiography of the candidate. The remainder of the written exercise consists in examination of the various branches of medicine, surgery, and hygiene. The oral examination includes subjects of preliminary education, history, literature, and natural sciences. The clinical examination is conducted at a hospital, and when practicable, candidates are required to perform surgical operations on a cadaver. Successful candidates will be numbered according to their attainments on examination, and will be commissioned in the same order as vacancies occur. Upon appointment the young officers are, as a rule, first assigned to duty at one of the large hospitals, as at Boston, New York, New Orleans, Chicago, or San Francisco. After five years' service, assistant surgeons are entitled to examination for promotion to the grade of passed assistant surgeon. Promotion to the grade of surgeon is made according to seniority, and after due examination as vacancies occur in that grade. Assistant surgeons receive $1,600, passed assistant surgeons $2,000, and surgeons $2,500 a year. When quarters are not provided, commutation at the rate of thirty, forty, and fifty dollars a month, according to grade, is allowed. All grades above that of assistant surgeon receive longevity pay, 10 per cent. in addition to the regular salary for every five years' service up to 40 per cent. after twenty years' service. The tenure of office is permanent. Officers traveling under orders are allowed actual expenses. For further information, or for invitation to appear before the board of examiners, prospective candidates may address the Surgeon-General, Public Health and Marine Hospital Service, Washington, D. C.

Pasteurization Bill Introduced.—A bill providing for the pasteurization of all milk sold in New York City has been introduced before the Assembly at Albany. By the operation of the measure, the dealing in and selling of any milk in New York City which has not been pasteurized would bring upon the parties handling the milk imprisonment for not less than six months, or a fine of $500, or both. It is provided that the Commissioner of Health shall designate pasteurizing stations to which every quart of milk brought into the city must be taken and put through the process of pasteurization, and that the city must construct such stations. Following the process, a stamp will be put on the receptacle by the health authorities, whereupon the dairy and milk companies and any others whose milk has been subjected to the process may take their milk and start on the delivery thereof. Provision is made for the confiscation and destruction of any milk found to be unpasteurized. Authority is also given for the appointment of a large number of additional milk inspectors. The bill is too sweeping in its provisions, for some of the milk supplied to the city is pure and should not be pasteurized.

Hospital Transfers.—Coroner Harburger of this city, in the course of the discussion before the Assembly Committee at Albany of the Huth bill, a measure providing for the curtailment of the practice of transferring patients from one hospital to another on the alleged ground that this is resorted to in order to keep down the mortality records of the institutions, made the astonishing statement that 15,000 patients yearly are transferred from hospitals while in a precarious condition, and that 5,000 deaths annually are attributable to this cause.

Children's Hospital Society of Chicago.—This Society, with its executive board chosen from the ranks of physicians and those who are acquainted with the conditions, in the few years of its existence has more than doubled the number of beds for children in hospitals, has improved the methods of care, and has secured the cooperation of first rate hospitals and all the prominent charity organizations, and may call upon them for aid from its central office in the downtown district. It not only sees that sick children among the poor have places in hospitals, but it finds homes for the neglected child, shelters for the street boy, and through a milk commission provides pure milk in the districts of tenement houses and has bettered the milk supply for the city, and is urging the foundation of a colony for epileptics. It has cared for 1,100 children in hospitals, and the number of those that seek its ministrations is constantly increasing.

Los Angeles Medical Library.—The formal dedication of the new Medical Library building presented to the Clinical Association of Los Angeles by Dr. W. Jarvis Barlow took place on February 8. Dr. Geo. F. Bovard, president of the University of Southern California, presided, and addresses were made by Dr. Barlow, Dr. Joseph Kurtz, president of the Clinical Association, and Dr. Milbank Johnsen, president of the Board of Trustees. The use of the library is free to all members of the profession, though to provide for its adequate maintenance three graded forms of membership have been decided upon.

Public Lectures on Problems of Insanity.—The fourth of the series of lectures on the above topic, arranged for by the Psychiatrical Society, will be delivered by Dr. Allan McLane Hamilton at the New York Academy of Medicine, on Saturday, March 2, at 8.30 P.M. The subject will be: "The Development of the Legal Regulations Concerning the Insane, with Suggestions for Reforms." The aim of these lectures is to place before the profession and leaders of sociological work the facts with regard to insanity, which point to the possibility and duty of initiating some broad movement with a view to preventive measures.

The Death Rate in England and Wales during 1905 was the lowest on record, and only four other European countries make a better showing. The deaths of fifty-eight reputed centenarians, forty-seven of whom were women, were reported during the year.

The Crocker-Doyen Suit.—The First Tribunal of the Seine on February 23 rendered its decision in the case of George Crocker against Dr. Doyen, by which Mr. Crocker sought to recover a $20,000 fee which he paid to the French surgeon in 1904 in the expectation that he could cure Mrs. Crocker of a cancer, alleging that Dr. Doyen obtained the large fee from him by "moral violence." The court held that the good faith of Dr. Doyen had been wrongly attacked and condemned the plaintiff to pay the costs of the action. The contract, it was pointed out, had been freely entered into by the parties concerned, and, therefore, could not be annulled unless Dr. Doyen failed to perform his duty, which was not the case, as he withdrew at Mr. Crocker's request and was ready at all times to resume his treatment of Mrs. Crocker. The court further declared that it could not decide the question of the reasonableness of the fee, but only that of the validity of the contract.

Counter Prescriber Prosecuted.—The first arrest under the New Jersey law providing against

the prescribing for sick persons by druggists was made last week in Bayonne, the City Physician, acting in behalf of the Health Board, being the complainant. The offending druggist pleaded ignorance of the law and was dismissed with a reprimand.

Centenarians.—A resident of Montreal, Canada, died on February 20 at the alleged age of 111 years. It is stated that he never had carried an umbrella and that he was a constant user of tobacco, smoking before breakfast every morning up to his last illness. The oldest inhabitant of North Carolina died on the same day in Waynesville at the reported age of 112 years. A daughter, aged ninety, survives him.

Multiple Pregnancy.—From Middlesborough, Ky., comes the report that the wife of a Polish miner living at Fort Ridge on February 21 gave birth to five children, three girls and two boys, who are all living.

Meningitis in Great Britain.—The number of cases of cerebrospinal meningitis in the Glasgow outbreak is now well over two hundred, and more than one hundred and nineteen deaths have been reported. In Edinburgh there have been twenty-five cases and twenty-one deaths. The total number of cases in Scotland this year exceeds three hundred, with a mortality of about fifty-five per cent. In addition, one hundred cases with fifty-five deaths have occurred in Belfast, and cases are also being reported from Liverpool.

Famine Conditions in Russia.—The Red Cross makes the statement that as the reports of the pitiable condition of the famine sufferers of Russia, who number from twenty to thirty millions, have been officially confirmed, the organization will actively engage in the collection of funds for their relief. The administration of the relief work will be carried out by the Russian Red Cross. Contributions should be made payable to and addressed to Red Cross, War Department, Washington, D. C.

Smallpox in Missouri.—Four persons attached to the House of Representatives in Jefferson City are down with smallpox, the infection having been conveyed, it is thought, through a member of the House who was taken ill during a session and was discovered to be suffering from the disease. The Jefferson City Board of Health states that there are thirty cases in the city.

Trichinosis on the East Side.—Eight cases of trichinosis have lately come under observation in Bellevue Hospital, all of the patients being residents of the neighborhood around First avenue and Third street.

Mica Post Cards Not Mailable.—The Post-Office authorities have decided that post cards ornamented with particles of mica, glass, or similar substance are likely to cause injury to the postal employees either through inhalation of the detached particles or in other ways, and they have accordingly been excluded from the mails unless inclosed in envelopes.

Home for the Destitute Blind.—A concert for the benefit of the Home for the Destitute Blind will be given at the Waldorf-Astoria on Monday, March 4, at 3.30 P.M. Attached to the institution is a workshop for the blind inmates, and the purpose of the concert is to aid in enlarging this shop. All the expenses of the concert will be met by some of the managers of the home, and the entire proceeds will go to the charity.

Dr. Edward W. Ryerson was recently appointed attending orthopedic surgeon at St. Luke's Hospital and orthopedic surgeon at the Children's Memorial Hospital, Chicago.

Dr. Walter J. Marciey, former superintendent of the Massachusetts State Sanatorium in Rutland, was presented a loving cup by patients, former patients, officers, and employees of the institution recently.

Dr. Seymour Oppenheimer has bee laryngologist and otologist to the Syd pital.

No Canteen for Soldiers' Homes.— of Representatives, on February 23 by a vote of ninety-one to eighty-six, adopted an amendment to the Sunday civil bill providing for the abolition of the canteen in all national homes for disabled soldiers. This was in spite of the statements of governors of homes, chaplains, surgeons, and other officials favoring the maintenance of the canteen, which had been presented to the Committee on Appropriations.

Coming Events Cast Their Shadows Before.—The following is from the recent presidential address of Dr. Joseph Decatur Bryant, ex-President of the Medical Society of the State of New York, but President-elect of the American Medical Association: "The editorial policy of a journal of mutual constituent ownership, like this of ours [the *New York State Journal of Medicine*], should be guided by the composite wisdom of an impartial committee chosen for the purpose, rather than by the notions of the editor himself, as in the instance of personal proprietorship."

National Association for the Study and Prevention of Tuberculosis.—The third annual meeting of this association will be held at the New Willard Hotel, Washington, D. C., May 6, 7, and 8. The organization of the sections for the meeting is as follows: Sociological Section, Mr. Paul Kennaday, New York, Chairman; Mr. Christopher Easton, New York, Secretary; Clinical and Climatological Section, Dr. George Dock, Ann Arbor, Chairman; Dr. Joseph Walsh, Philadelphia, Secretary; Pathological and Bacteriological Section, Dr. F. F. Wesbrook, Minneapolis, Chairman; Surgical Section, Dr. W. S. Halsted, Baltimore, Chairman; Dr. Hugh H. Young, Baltimore, Secretary; Section of Tuberculosis in Children, Dr. T. M. Rotch, Boston, Chairman.

The New York Physicotherapeutic Association.—An association bearing this title was organized on February 1, 1907, by the adoption of a constitution and by-laws, and the election of the following officers: *President*, Albert C. Geyser, M.D.; *Vice-President*, W. L. Heeve, M.D.; *Secretary and Treasurer*, Hills Cole, M.D. The following were present at this organization meeting: Drs. Brinckman, Boskowitz, Hills Cole, Geyser, W. L. Heeve, Wm. Harvey King, and H. E. Waite; and these together with Drs. Dieffenbach, Meacham, and Sillo will be the charter members. The constitution provides for active, associate, and regular honorary members. Active membership is opened to legally qualified practitioners of medicine and surgery in good standing, practising in New York City or its vicinity. Meetings will be held on the second Friday of each month, except in July, August, and September. The dues are two dollars a year.

Cincinnati Academy of Medicine.—Dr. Geo. W. Crile of Cleveland, Professor of Surgery in the Western Reserve University and Surgeon to the Lakeside Hospital, was entertained by the Cincinnati Academy of Medicine on February 18, 1907. Dr. Crile addressed the society on "An Experimental

and Clinical Research on Direct Transfusion of Blood." He described some brilliant results of his experimentation in this direction, and reported cases in detail. The academy will hold its annual election of officers on March 4, and a banquet celebrating its semi-centennial on March 5, at the New Hotel Sinton. The valedictory of the retiring officers and inaugural of the incoming officers will take place on March 11.

[illegible]erence.—A meeting of the Hospi[illegible] was held at the New York Acade[illegible]e, on Wednesday, February 27, at [illegible]M. The following special program [illegible]pared: "The Milk Supply of a Hospital," Dr. S. T. Armstrong, General Medical Superintendent, Bellevue and Allied Hospitals. "How Should the Ambulance Service of Greater New York Be Organized?" Mr. Homer Folks, Secretary, State Charities Aid Association.

National Association for the Study of Epilepsy and the Care and Treatment of Epileptics.—The next meeting of this association is, by invitation of the General Board of Directors of the State Hospitals of Virginia, to be held in Richmond on October 23 and 24. A specially attractive program will be offered, so arranged by topics that it will be convenient for each member to attend to the reading and discussion of such portions as especially interest him, while it will also allow opportunity for each person to see something of the Jamestown Exposition, before, during, or after the meetings. Those intending to present papers at the meeting are requested to communicate promptly with the secretary, Dr. J. F. Munson, Sonyea, N. Y.

Congress of Polish Physicians and Scientists.—The tenth Congress of Polish Physicians and Scientists will be held at Lemberg, Austria-Poland, July 22 to 25, 1907. Dr. Francis E. Fronczak of Buffalo is to represent America at the Congress.

Mississippi County (Ark.) Medical Society.—At the recent meeting of this society, held in Blytheville, officers were elected as follows: *President*, Dr. C. C. Stevens of Blytheville; *Vice-President*, Dr. O. Howton of Osceola; *Secretary and Treasurer*, Dr. T. G. Brewer, Osceola.

The "Long Island Medical Journal."—Under the editorship of Dr. Paul M. Pilcher this new and attractive publication makes its appearance in place of the *Brooklyn Medical Journal*. The *Journal* publishes the Transactions of the Associated Physicians of Long Island, the Brooklyn Surgical Society, and the Brooklyn Pathological Society. The initial number was devoted to the surgery of the peritoneum and the current issue is devoted to a discussion of anesthesia. It has been rebuked by the Secretary-Editor of the *Journal of the American Medical Association* because of the advertisements it carries, but as Dr. Bryant, the President-elect of the Association, is being roundly scolded by one of the official State medical journals because he tacitly approves of the "unethical" advertisements in the *New York State Journal of Medicine*, the honors seem to be easy.

Clinics at the Elgin (Illinois) Insane Asylum.—Recently Speaker Shurtleff of the Illinois Legislature introduced resolutions which aimed at the prohibition of clinics in the Hospital for the Insane at Elgin.

Obituary Notes.—Dr. J. Clark Thomas of this city died in Los Angeles, Cal., on February 20 at the age of sixty-three years. He was graduated from Yale in 1864 and four years later received his medical degree from the College of Physicians and Surgeons in this city. He served as interne in Bellevue Hospital and had practised in this city for about thirty-five years.

Dr. George H. Nichols of Brooklyn died suddenly on February 17 in Stamford, Conn. He was born in Plainfield, N. J., in 1863, and was graduated from the University of New York. Four years ago he was appointed a member of the Board of Education.

Dr. A. R. Alley of Atlanta, Ga., died on February 21 at the age of sixty-three years. He was a Confederate veteran and had practised in Atlanta for many years.

Dr. Joseph O'Shea of Paterson, N. J., died on February 20 of tuberculosis at the age of thirty-three years. He was a graduate of Seton Hall College and received his medical diploma from the Bellevue Hospital Medical School in 1896. He had been for four years medical school inspector.

Dr. Henry Z. Gill of Long Beach, Cal., died on February 7 at the age of seventy-six years. He occupied several medical posts during the Civil War and in 1864 was made surgeon-in-chief of the First Division of the 20th Army Corps, with the rank of Lieutenant-Colonel. He wrote a surgical history of the Civil War and a work on the Confederate prisons. He had been a resident of Long Beach for about five years.

Dr. F. S. Cowles of Essex, Conn., died on February 12 at the age of thirty-seven years. He was born in Rome, N. Y., and received his professional education in the Yale Medical School. He practised for a time in Durham, Conn., and about four years ago removed to Essex.

Dr. Thomas M. Woodson of Gallatin, Tenn., died on February 12 at the age of seventy-eight years. He was graduated from the University of Louisville and practised in Bethpage, Tenn., until 1874, when he removed to Gallatin. He retired from active life about five years ago on account of ill health.

Dr. William A. Butman of Somerville, Mass., died on February 11 of pneumonia. He was born in Fairhaven in 1869 and received his medical education from the University of Baltimore. He practised for a time in Boston and removed to Somerville a short time ago.

Dr. Oscar Gaudet of Convent, La., died on February 7 at the age of sixty-eight years. He was a graduate of the University of Virginia and served in the Confederate Army. At the close of the war he began practice in St. James' parish and served a number of terms as coroner of the parish.

Dr. J. T. Marsh of Kansas City, Mo., died on February 9. He was born in Clay County in 1833 and was graduated from William Jewel College and Westminster College, Fulton, Mo. He had practised in Kansas City for over forty-five years.

Dr. C. B. Greenfield died in Honokaa, Hawaii, on January 18 at the age of sixty-three years. He was born in England and was a former surgeon in the Royal Navy. He had lived in the islands many years.

Dr. Frank W. Talley died at Philadelphia on February 17 at the age of forty-two years. He was graduated from the medical department of the University of Pennsylvania in the class of 1887 and subsequently served as resident physician in the Philadelphia Hospital. He pursued post-graduate studies abroad and on returning became assistant in gynecology in the Philadelphia Polyclinic and gynecologist to St. Agnes Hospital.

Dr. Ellerslie Wallace died at Philadelphia on February 17 at the age of fifty-eight years. He was a son of the distinguished obstetrician of the same name, who was formerly professor of obstetrics in Jefferson Medical College.

NINTH HARVEY SOCIETY LECTURE.

The ninth of the present series of lectures under the auspices of the Harvey Society was held at the Academy of Medicine on Saturday, February 23, the speaker being Prof. W. J. Councilman of the Harvard Medical School. The title of the lecture, as it had appeared on the announcements, was: "The Relation of Certain Leucocytes to Infectious Diseases," but this was changed by the lecturer to "Some Changes in Lymphoid Tissue in Certain Infectious Diseases." The original title was very misleading and certainly gave no clue to the subject matter of the lecture, which was a highly finished pathological study along morphological lines.

The speaker began by saying that as long ago as 1898 he had called attention to a form of nephritis associated with acute infectious diseases. The condition had been described by others previously, but not sufficient attention had been paid to the subject. The speaker then gave a very lucid account of the morphological changes which such a kidney manifested. Among these were areas of greater or less diameter which projected above the cut surface. These areas were usually situated in the cortex, which frequently was three or four times the usual thickness. The size and weight of the kidney were occasionally enormously increased, though, as a rule, the increase was only slight. On section an opaque milky fluid exuded. The areas protruding above the cut surface were found to consist of a deposit of lymphoid cells. These cells varied considerably, but could in general be divided into three classes: (1) Small lymphoid cells of the usual type; (2) the most numerous type were cells varying from 6 to 15 microns, and having a rather vesicular nucleus usually placed eccentrically; (3) cells corresponding to plasma cells.

Prof. Councilman described each type in detail, giving the staining, reactions, etc. None of the cells showed any characteristically staining granules. All of them were ameboid, the lymphoid type cell probably the least so.

The areas were truly cell deposits, for cells of this type were not found in the kidney tissue. Similar interstitial deposits of lymphoid cells were also frequently found in the adrenal and sometimes in the pancreas and in the lungs. They were most common in children in infections of diphtheria, scarlet fever, and smallpox.

The immense accumulation of these cells led to a disorganization of the tissues, though often the latter appeared entirely normal. The presence of mitotic figures was evidence of rapid proliferation after they had been deposited. Since these cells could not originate locally they must come from the blood. At first Councilman believed that the reason for their deposit was mechanical, due to conditions of pressure in the blood-vessels. He now believed that there was a positive chemotaxis which attracted the cells and led to their deposit.

The cells described above had not been described by the hematologists. The nearest approach to them was perhaps the cell described by Türck under the name of irritation cells. They had no specific granules, were mononuclear, and according to Türck, originated in the bone marrow. Prof. Councilman believed that the cells he had described originated in the lymphoid tissues, and went on to describe in detail the structure of lymph nodes. In these, among other cells, were found certain masses of cells which had first been carefully described by His and later by Flemming. His regarded them as masses of germinal cells. They were more abundant in young children, later in life the lymphoid tissue was much less active. The transition between the germinal cells and the small lymphoid cells could be traced.

Oertel had been the first to show that in diphtheria there were small foci of necrosis in the lymph nodes and that these corresponded to the germinal masses. A similar condition had since been found in scarlet fever. The destruction of the cells in these cases was due not only to the vulnerability of the cells, but to the large capillary supply leading to considerable transudation. With this destruction there was an accumulation of phagocytic cells in the form of a nodule, which looked something like a miliary tubercle. It did not, however, caseate. Most marked changes were found in the germinal cells in the tonsils.

During this time the lymph nodes showed evidences of marked activity. The new formed cells entered the blood-vessels, since they were all ameboid. From the blood-vessels they passed into the various tissues, forming interstitial foci, especially in the kidney, liver, and adrenal body.

The speaker continued by considering the lymphoid cells as they occurred in the blood. He spoke of the various theories and schemes which the various hematologists had devised and which, after all, were nothing but theories. He discussed the three types of cells, polynuclear, lymphocytic, and transitional, and pointed out that the great difference between the two former was that the lymphocytic were never phagocytic. The phagocytosis of the polynuclear was eminently microbic, that of the transitional cell chiefly cellular. He stated that an indifferent cell was apparently the parent of both the myelocytic and the lymphocytic type. The type produced would seem to depend on the location.

Correspondence.

THE RADICAL CURE OF TRIGEMINAL NEURALGIA.

To the Editor of the Medical Record:

Sir:—In your issue of February 23, Dr. M. Allen Starr endeavors to correct many of the "errors" in my article on "The Radical Cure of Trigeminal Neuralgia by Means of Peripheral Operations," published in the Medical Record of February 16. In the opening sentence of that paper I referred to a previous communication, entitled "The Surgical Treatment of Trigeminal Neuralgia," which appeared in the Medical Record of September 29, 1906. This paper discussed in greater detail points that appear in summary in the subsequent report. I am sure that, had Dr. Starr taken the trouble to read this, he would have found his criticisms in a large measure answered. I shall, however, take each of his statements singly, and discuss them in order.

1. After first introducing one of my conclusions, "We know nothing of the pathological anatomy of trigeminal neuralgia," Dr. Starr says: "This statement ignores the very complete and positive results published by Keen and Spiller." I did not intend to imply when I said that "we know nothing of the pathology of trigeminal neuralgia" that no work had been done upon this subject. When I set out to write my original article, I collected upon the subject of pathology of trigeminal neuralgia alone a page and a half of references on this subject. I read over and summarized the most important of these articles, twenty-eight in number, and reported them with references in my original communication of September 29, 1906. I found that the opinions were divided about equally as to whether the disease lies in the Gasserian ganglion or in the peripheral nerves, or whether any pathological changes exist at all. In reading over these reports, one fact is strikingly apparent, namely, that no two observers agree, and that,

therefore, there are as many views on the pathology of trigeminal neuralgia as there have been investigators. Now, it is a well recognized axiom in medicine that wherever there are many views or theories about a disease, none is conclusive. It is therefore not an illegitimate conclusion to say that "we know nothing of the pathology of the disease." Coming more specifically to Dr. Starr's statement that I "ignore the very complete and positive results published by Keen and Spiller, and subsequently confirmed by them, and by Thomas, and by Redlich," I shall not deny that the changes observed by Keen and Spiller were noted by them. In my original article of September 29 I quoted the results of Keen and Spiller, and even stated their conclusions in their own words. It is interesting, however, to learn that Dr. Starr finds their results "complete and positive." If these findings are "complete and positive," and the disease lies within the Gasserian ganglion, why did Keen subsequently advise merely division of the sensory root for the cure of trigeminal neuralgia? Also, why have their observations not been confirmed and accepted by subsequent observers too numerous to mention? I need only name, among others, such observers as Hutchinson and Cushing. The statements of these authors are particularly interesting because they are advocates of the intracranial operations. Cushing says: "No lesion sufficiently characteristic to consider it typical of a particular disease is present." Nor can it be overlooked, as has been pointed out by other observers, that the changes in the Gasserian ganglion or peripheral nerves may be secondary products, and not primary. These secondary influences may be (1) traumatism, due to the necessary manipulations in the course of extirpation; (2) incomplete preservation of the ganglion; (3) the age of the patient; this could easily account for the endarteritis; (4) ascending changes in the nerve or ganglion as the result of previous peripheral operations. It is rather significant that Monari,[1] Schwab,[2] and Coenen[3] found absolutely normal ganglia in those cases in which no previous peripheral operation had been performed.

To quote the observations of Thomas and of Redlich (these studies incidentally were upon tabetic subjects, and are therefore entirely irrelevant) is entirely a matter of personal taste. We might just as well quote the names of any one of the numerous workers in our list of references, many of them in the first rank of neuropathologists, whose findings have differed from those of Keen and Spiller, Thomas, etc. Not until some definite picture of the lesion in trigeminal neuralgia has been accepted by neurologists will we admit that we know the pathology of trigeminal neuralgia. This condition of affairs, however, is far from the case at present; nevertheless, if Dr. Starr is willing to accept the conclusions of the authors whom he quotes, well and good. The whole question is an academic one, and, as we shall see, has little bearing on the practical issue in question.

2. Dr. Starr quotes again my words: "All proof is lacking that the neuralgia originates in the Gasserian ganglion." In reply he says: "There can be no better proof than the fact, of which I have personal experience in more than a dozen cases, that when operations upon the peripheral branches of the trigeminal nerve fail to relieve (as they always do fail to give permanent relief), an excision of the Gasserian ganglion or a division of the root of the fifth nerve between the ganglion and the pons always cures." To say that, because removal of the Gasserian ganglion abolishes the pain, therefore the ganglion is the seat of the disease, is an argument that is by no means warranted. It is rather surprising to note that Dr. Starr shatters his own argument by the very next phrase, "division of the root of the fifth nerve between the ganglion and the pons always cures." The reason why this operation and the extirpation of the ganglion cures is because the *sensory impulses have been cut off*. This is also the reason why division of the peripheral branches invariably brings about relief. I claim, and I am not alone in this respect, that the reason why peripheral operations fail to give permanent relief is because sensory impulses in time become restored by the regeneration and reunion of the divided nerve. If the disease is in the Gasserian ganglion, how can Dr. Starr explain the temporary relief by peripheral operations at all? And how, also, can he explain the comparative freedom from neuralgia of the ophthalmic division?

3. Dr. Starr states, "I have never seen a relapse when the ganglion was completely and properly removed, etc." Dr. Starr may not have seen such a relapse, but I have collected from the literature the reports of nine cases. Of these, two are reported by Krause himself—a "competent surgeon"—whom Dr. Starr quotes as not having had recurrences. In one case reported by Perthes (*Deutsche Zeitschrift f. Chirurgie*, Vol. LXXVIII.) no less a pathologist than Marchand confirmed the findings.

4. Dr. Starr says, "These statements refute absolutely the other assertions of Dr. Moschcowitz, which therefore require no notice." Granted—if Dr. Starr's claims are granted—but most emphatically not granted if his other claims are not granted.

5. Dr. Starr says, "Dr. Moschcowitz claims that it is to the regeneration of the peripheral nerve that recurrence of pain is due. That may be true, but I have cases on my records where the pain has recurred after peripheral operation too soon to be due to regeneration." How soon? What proof does Dr. Starr offer that the nerve did not regenerate? Dr. Starr may be unacquainted with the fact that nerve regeneration may, and does take place in as short a time as two weeks. (Ramon y Cajal: Comptes rendus de la Société de Biologie, Vol. LIX., pages 420 and 422.) This whole statement of Dr. Starr is not sufficiently specific.

6. Dr. Starr says, "and other cases where it has recurred when a half inch of the nerve has been resected." That Dr. Starr would regard the resection of even as much as a half inch of nerve, as precluding the possibility of regeneration, indicates that he is unacquainted with one of the earliest discovered facts in regard to regeneration of the peripheral nerves. As long ago as 1845, Dieffenbach abandoned his method of peripheral resection of large segments just because of this regeneration. In one of my early cases complete regeneration of the inferior dental nerve occurred after resection of one inch. Complete regenerations have been found after evulsions of the entire nerve distally to the foramina at the base of the skull. Perthes (*loc. cit.*) experimentally found regeneration after extirpation of 9.5 cm.

7. Dr. Starr says he has seen other cases "in which pain has returned, and at the radical operation no evidence of regeneration or union of the formerly divided peripheral branch has been found." In the first place, I fail to see how an intracranial operation can reveal a condition in such distant parts as the infraorbital or inferior dental canals. Secondly, I have failed to find one authentic instance in literature in which recurrence after peripheral operation took place without regeneration of the nerves. The cases of Dr. Starr should, therefore, be reported in greater detail.

8. Dr. Starr says, evidently in a spirit of adverse criticism, that "the cases cited by Dr. Moschcowitz are both too few in number and are reported far too soon to afford any convincing proof of his statement." Compare this with my conclusion; and was I not just as critical of myself when I said that "I do not present these cases as cured cases of trigeminal neuralgia; the period of observation is altogether too short to admit of this deduction"?

Excluding all the more purely theoretical questions in the issue, three facts in regard to the practical treatment of trigeminal neuralgia stand out, and these Dr. Starr cannot deny: (1) The intracranial operation of Hartley and Krause is one of the severest in surgery, and is attended by a formidable mortality. (2) Everybody agrees that peripheral division of the nerves is attended in every case by temporary freedom from pain in the affected nerves. (3) The peripheral operation is practically free from risk. These considerations, and also the apparent possibility of producing radical cures by peripheral operations, have led surgeons in recent years to turn more and more to the peripheral operations for trigeminal neuralgia, as anyone who has followed the recent literature may note. These recent peripheral operations fall into two groups: (1) those in which no measures are taken to prevent regeneration of the nerves, and (2) those in which measures are taken to prevent regeneration. In the first group we need mention only the methods of Murphy, who advocates the injection of osmic acid; of Laplace, who has resuscitated the evulsion method of Thiersch, and of Schlosser and Kiliani, who advise alcohol injections into the affected nerves. In the second group comes, first of all, the method of Abbe (which, although an intracranial operation, is really peripheral), Perthes, and finally C. H. Mayo. The latter (Peripheral *versus* Intracranial Operations for Tic Douloureux; *Surgery, Gynecology, and Obstetrics*, December, 1906)—surely a competent surgeon—has been using practically the same method that I have described, and moreover performed his first operation long before I published my first report. He reports one case in which freedom from pain existed for a period of seven years; a period that ought to satisfy even Dr. Starr's most exacting conditions. This case is doubly interesting because at the end of this time recurrence ensued, and at the second operation the plug that Dr. Mayo had introduced into the infraorbital canal was found to have slipped out, and the nerve had regenerated.

A. V. Moschcowitz, M.D.

THE SPECIFIC GRAVITY OF URINE.

To the Editor of the Medical Record:

Sir:—In your issue of February 16 you refer editorially to a letter by Dr. A. W. Brand to the *Lancet* of January 26, in which the writer calls attention to the fact that the specific gravity of the urine varies greatly with its temperature, and states that he has found no allusion to this in any text-book of physiology or clinical medicine.

That this is not an original observation may be seen by reference to the sixth edition of the work of Dr. Charles W. Purdy on "Practical Uranalysis," page 14, wherein is stated: "The temperature of the urine immediately after being voided ranges from 85° to 95° F (29.5° to 35° C.); therefore, in taking the specific gravity of freshly-voided urine, before cooling, its temperature should be observed, and for every seven degrees of temperature the thermometer indicates above that upon which the instrument is standardized, one degree should be added to the specific gravity of the urine, in addition to that indicated by the instrument."

In this connection it may not be amiss to allude to the fact that the specific gravity tests as ordinarily made with the so-called urinometer are so fallacious as to possess very little, if any, scientific value. The instruments themselves are frequently inaccurate, the readings are taken hastily, and no allowance is made for the temperature or for the conditions under which the specimen is voided, as to time, preceding diet, etc. It is the exception, rather than the rule, for the twenty-four-hour average specimen to be tested. Under these circumstances, I contend that the specific gravity observation is practically useless, and might as well be relegated to the rubbish-heap of other perfunctory measures.

Properly carried out, with a balance of the Mohr, Westphal, or Sartorius type and a Wiemann thermometer, using a twenty-four-hour average specimen, the specific gravity reading may be a most valuable source of information, both alone and in conjunction with other findings; but I wish to emphasize the fact that its value is in direct proportion to its accuracy, and unless to it is given the same painstaking care in its estimation that is accorded to other laboratory methods, and unless equally delicate apparatus is employed, it is manifestly improper to expect of it the same measure of results. Gilbert Geoffrey Cottam, M.D.

OUR LONDON LETTER.

(From Our Special Correspondent.)

CANCER—TUBERCULOSIS COMMISSION—RED CROSS WORK—IMMUNIZATION DEPARTMENTS FOR HOSPITALS PROPOSED—MILK SUPPLY—AFTER-CARE ASSOCIATION—CEREBROSPINAL MENINGITIS—ITEMS.

London, February 8, 1907.

Cancer in its various respects is still a leading subject in all directions. Dr. Bashford, superintendent of the Imperial Research Fund, in an address at the Epidemiological Society, has drawn attention to the real and apparent differences in the incidence of the disease. Contrary to a common statement, he pointed out that cancer was approximately as frequent a cause of death in Japan as in England, and the notion of its being a result of European civilization was thereby negatived. One phenomenon of universal occurrence in man and animals had more importance than all variations. The increasing frequency of cancer in advancing age was a law applicable to the vertebrates, whether short or long-lived. In childhood the law obtained as to fatal structures. The investigation of cancer could be profitably carried on from the standpoint that (1) its incidence obeyed the definite biological laws which governed the growth and length of life of organisms as a whole or of their individual organs, because it arose *de novo* in each sporadic case; or that (2) sporadic cases are connected by an infecting virus which produces its effects in conformity with the same biological law. The apparent increase in the number of deaths in this country is to be attributed to more accurate diagnosis, and differences in localities may be due to varying age distribution of the population. The differences between several countries in this respect were just those of the accuracy of their vital statistics. The great mortality rate of Switzerland, for instance, is probably explained by the rule that a medical inspection of the body is made. But as the only trustworthy estimation of the frequency of cancer is the national death rate, the collaboration of the Registrar-General's office is most valuable and this has been given freely, and Dr. Bashford acknowledged his indebtedness for it.

Dr. Tatham, president, remarked that though there was little hope that primary growths would be amenable to other treatment than removal, the fact that animals could be rendered unsuitable for the growth of malignant tumors was important, as it might eventually be found that cells disseminated from the site of entrance might be rendered unable to grow. Experimental transference of cancer from one individual to another was no longer to be doubted, but it quite contraindicated expectations, as it was easier to effect in young than old animals. It would, therefore, seem that the frequency in later life was not due to increasing suitability of the soil. Mice could be protected by previous inoculation of cancerous tissue from another mouse, but not from an animal of a different species. It was still more surprising that protection could be obtained by inoculation of healthy tissue, blood, in fact, from one healthy animal into another of the same species. That fact was pregnant with possibilities.

Dr. Payne said it was surprising to find young animals more susceptible than old. Statistics showed indeed a high mortality rate in early life, but he considered that was really due to sarcoma. In reference to the returns of primary cancer of the liver he also thought many of the cases were really secondary.

Dr. Newsholme said statistics proved civilization was not a factor in causation of cancer, nor was meat eating. In fish and animals it occurred in about the same proportion as in man.

Sir Shirley Murphy said the incidence was about the same in rich and poor.

Dr. Dawson Williams said all through fetal life obsolescence of certain tissues was going on and the process continued after birth.

Dr. J. A. Murray gave a microscopical demonstration of experimental and of sporadic cancer in mice.

Writing in *The Hospital*, Dr. Shaw-Mackenzie, who has devoted so much attention to the treatment of cancer, considers the parasitic theory as dead and that the solution of the etiology of the disease will eventually be found in the chemicobiological theory. But considering how our knowledge of cancer is environed with ambiguity springing from undetermined facts, he supports the suggestion made by Mr. Percy Dunn in the *Nineteenth Century* (1893) for the appointment of a Royal Commission on the disease, and goes so far as to say that if such an inquiry had been appointed some years ago we should now have been in possession of information of which use could be made in a preventive sense.

That the parasitic theory is by no means dead is, however, maintained by many. Among them Mr. Jackson Clarke still holds the view he has so long urged that sarcoma and cancer are caused by parasitic protozoa, the study of which he says enabled Schaudinn to discover the microbe of syphilis. The sections of sarcomas in dogs made by the late Dr. Washbourn he still believes to be such in opposition to the views expressed in the report of the Imperial Research Fund.

A second interim report of the Royal Commission on Tuberculosis has been issued. It states that there can be no doubt that in a certain number of cases, especially in children, the disease is the direct result of the introduction of the bacillus of bovine tuberculosis and in the majority of cases this is through cow's milk. Clearly cow's milk containing the bovine bacillus is a cause of fatal tuberculosis in man. Of 60 cases of human tuberculosis investigated 14 were traced to this cause. If attention is confined to cases in which the bacilli were apparently introduced through the alimentary canal, the proportion is much larger. Of the 60 cases the clinical histories indicated this entrance in 28. Of 9 cases in which the cervical glands and of 10 in which the abdominal lesions were studied, 10 showed the bovine bacillus. It is pointed out that the bovine bacillus can be detected, though with some difficulty, in milk. There is less difficulty in recognizing clinically tuberculosis in the cow, and a cow so suffering may yield tuberculous milk. The results point to the necessity of more stringent measures to prevent the sale of such milk.

The rôle of Red Cross Societies was the subject of an address on Wednesday at the Royal United Service Institution by Lt.-Col. Macpherson, R.A.M.C., who sketched the official organization of the care of the sick and wounded, instancing that of the Japanese which he had seen at work in the late war and declared to be a magnificent and efficient machine. Voluntary aid played no part at the front, but a real part at home. The outburst of sentiment in the event of a great national war had to find a vent, and the Red Cross Society collected and retained the flood till it could be utilized to the best advantage. The organizations of European countries having been described, he turned to that of Japan, where, he said, groups of relief or nursing sections were formed, each of 2 doctors, 1 apothecary, 1 accountant, 2 superintendent nurses, and 20 nurses. Each such group could take over 100 patients. At the outbreak of the late war

116 groups were ready, by the end 150. The female sections were 98. In Japan 1 in 45 of the population was a member of a Red Cross Society. None of the work was in the zone of the field army, very little in the line of communications, but 32 male groups did service there or at base hospitals. The peace work of Red Cross societies was to keep ready for mobilization, also to aid in case of a public calamity. Col. Macpherson found in this country excellent material and splendid peace organizations, *e.g.*, St. John's Ambulance Association, the Army Nursing Reserve, the Soldiers' and Sailors' Help Society, the St. Andrew's Ambulance Association, and the British Red Cross Society lent those bodies the required coordination and consolidation of their work. Still more the mode of keeping them in touch with the military authorities in time of peace should be carefully studied.

Sir A. E. Wright addressed a distinguished audience at the Royal Institution on the desirability of establishing at every hospital a department of inoculation or immunization. He told them it was as uncivilized to be carried off by bacterial diseases as to be devoured by wolves, and yet no serious effort had been made to get rid of such diseases. Practically all the work in that direction had taken the form of hygienic precautions. Inoculation was used against smallpox, but that was merely like a nation taking steps to defend itself against only one enemy. The white blood corpuscles had become famous under the name of phagocytes, because of their power of eating bacteria, but this function was very limited if the bacteria were presented to them in a so-to-say raw state. They needed cooking. It had been known for some time that the blood contained three elements which could be said to cook bacteria. A fourth had been discovered by himself and Dr. Douglas which they had named opsonin. Bacterial therapeutics should aim at increasing all four, and he therefore hoped to see an inoculation or immunization department set up by every hospital.

Dr. Cameron, M.O.H. for Leeds, reports the result of an investigation as to the milk supply of the city. He finds a remarkable disparity between the ordinary supply and cooled milk from perfectly healthy cows. In the latter when fresh there were 16,000 germs to a cubic centimeter. In samples taken from shops and railway stations there were 145,000 per c.c. In each case when the milk was just over a day old the number had enormously increased up to 224,000 and 10,000,000 respectively. In regard to tuberculous milk Dr. Cameron reports that by carefully inspecting all cows in the city at frequent intervals the disease had been practically stamped out among the animals, but that was not so in the country farms from which much larger quantities of milk were brought. Until municipalities had power to inspect farms outside their boundaries it would be almost impossible to check the evil. Here is a plain lesson for legislators.

The Worshipful Company of Apothecaries lent their hall for a meeting of the After-Care Association, which was established in 1879 to help poor persons discharged from lunatic asylums. Mr. Parker Young, the master of the company, presided, and was supported by Drs. Wilks and Gorden Brown (wardens) and other influential persons. He described the work and declared no charity was doing more good in a quiet way. It was true the sum spent on individual cases was large, but that was unavoidable, considering the difficulties surrounding the after-care of the insane. Drs. Savage, Blandford, Omsden, and Jones spoke in support of the work, the last named declaring that one out of every ten discharged from lunatic asylums was absolutely friendless. The Bishop of Barking testified as an East End clergyman to the care and wisdom displayed by the association in its prosecution of inquiries. The report was adopted and the council reappointed.

Cerebrospinal meningitis has spread during the week. It has effected a lodgment at Liverpool now; three cases were reported yesterday to the Health Committee of the city. The medical officer of health has issued a memorandum on the disease, advising immediate notification with isolation of both patients and suspects.

At Edinburgh on Tuesday it was stated that nine deaths had been certified since January 12, some of them being traced to Glasgow, in which city the Registrar-General's returns for the week ending on the 2d inst. reported sixteen deaths, as against twenty-two in the preceding week.

At Belfast up to February 1 there had been forty-five cases with nineteen deaths. As I told you the disease has been made notifiable there. An interesting report by Dr. Chalmers, Medical Officer of Health for Glasgow, deals with the disease in that city during the past six years.

A statement has been freely circulated this week that Dr. Donald MacAlister had been appointed principal of Glasgow University in succession to the late Principal Storey. This morning, however, the Press Association says it is requested by the Secretary for Scotland to say that the report is unauthorized. I suppose a short time will reveal the exact meaning to be attached to the phrase.

Dr. S. E. Cockey died at Frome on the 3d inst. in his ninetieth year.

OUR LETTER FROM THE PHILIPPINES.

(From Our Special Correspondent.)

THE MANILA MEDICAL SOCIETY—SATISFACTORY HEALTH CONDITIONS—CHOLERA—SMALLPOX—CEREBROSPINAL MENINGITIS—MALARIA AMONG THE PRISONERS IN THE IWAHIG SETTLEMENT—PERSONAL.

MANILA, January 14, 1907

INSTEAD of the regular monthly meeting of the Manila Medical Society, a business meeting was held January 7, 1907, for the purpose of electing new officers to serve for the ensuing year. Dr. Percy M. Ashburn, Captain and Assistant Surgeon, United States Army, member of the Board of Tropical Diseases, was elected President, and Dr. Ralph T. Edwards, Bacteriologist of the Bureau of Science, was reelected Secretary. Dr. Victor G. Heiser, Director of Health for the Philippine Islands, was elected a Councillor for five years.

The general health conditions in the Philippine Islands have improved so much during the past month that the Insular Bureau of Health, since January 1, 1907, discontinued the daily report of dangerous communicable diseases. This is the first time the health authorities have felt warranted in taking such a step for a period of over three years.

The last case of cholera occurred in Manila, November 28, 1906; the last case of plague, April 21, 1906, and, with the exception of one case of smallpox, the infection of which was a direct importation, there has been no case of this disease for a period of several months.

This satisfactory condition of affairs is no doubt the result of the permanent sanitary work which has been continuously carried out since the American occupation. The people of the islands are gradually being vaccinated, many artesian wells are being bored monthly, the pollution of water supplies is being corrected, the conditions of living are slowly improving, and the rigid quarantine inspection of foreign vessels by the Public Health and Marine Hospital Service is preventing the introduction of disease. So far as is known there has been no case of plague imported since 1900. On this account the insular health authorities have always felt that if the disease could once be eradicated from the islands, and subsequent cases promptly isolated, and other necessary measures taken, it would only be a question of a short time before the disease would disappear permanently from the islands. This happy result seems now to be an accomplished fact.

With regard to cholera, there are still numerous diverse opinions as to whether it is freshly imported each time, or whether the disease is indigenous in the Philippines.

The health conditions are probably better now than at any time since the American occupation, and also, no doubt, much better than they were for many years during the Spanish régime.

In spite of the favorable conditions with regard to public health, the native press still continues its attack upon the Bureau of Health. So far there appears to be no foundation for these attacks. The articles which are written usually contain nothing but personal abuse, and whenever a few items are published which have a semblance of reflecting upon the Bureau of Health, investigation has always shown the alleged facts to be untrue.

It is the general opinion among those who are well informed that the attacks are purely of a political nature; the ultimate object being to supplant the American personnel of the Bureau of Health with Filipinos, and in order to do this the aid of native newspapers has been invoked to discredit the American officials in the eyes of the masses.

The cruiser *Chattanooga* arrived in Manila from Shanghai, January 9, with a case of smallpox on board in the person of the paymaster's clerk. It is of medical interest to state that the entire personnel, including officers, were vaccinated several months ago, with the exception of the paymaster's clerk, who evaded the operation and is now apparently suffering the penalty. None of the balance of the personnel showed any evidence of having contracted the disease, although many of them must no doubt have been exposed to the same infection. The vessel was remanded to the Mariveles quarantine station for treatment.

The cruiser *Maryland*, which is one of the newer vessels of the navy, and one which has only recently arrived in the Philippines, has had a number of cases of cerebrospinal meningitis occur among the crew. The efforts which have been made so far to eradicate the infection

have not been successful, and cases still continue to occur. It is now proposed to send the vessel to the Mariveles quarantine station and have the personnel and ship thoroughly disinfected with the hope of removing the cause of the infection.

The prisoners who have been transferred to the Iwahig Penal Settlement on the island of Palawan have suffered severely from malarial fever during the past year. With a population of about 300, there have been an average of about one sixth of that number of cases per day in the hospital, with a pernicious type of malarial fever. It is understood that the Spanish authorities once attempted to use the same location for a similar purpose, but had to give up the plan on account of the malaria which they were unable to combat successfully. It will now be interesting to observe whether, in the light of recent discoveries, in connection with the prophylaxis against malaria, and carried out by an American administration, the prisoners at Iwahig can be kept in a healthy condition.

Dr. William J. Mallory, who has been in charge of the Benguet Sanitarium Division for the past two years, has obtained an extended leave of absence and has recently departed for the United States, via Europe.

Progress of Medical Science.

New York Medical Journal, February 6, 1907.

The Physical Processes of Immunity and Infection.—J. Wright believes that it is through the oropharynx and nasopharynx that the majority of pathogenic organisms gain access to the human system, and he has set out to investigate the physical factors involved in the struggle at this point between the invading germs and the natural barriers to their progress. Much has been learned in recent years concerning the reactions of protoplasm to various stimuli. The junction of the air and food tracts, whence all ingesta pass down to the organs of active metabolism, is the first battle ground. There must be some mechanism by which inert matter is allowed to pass while harmful living protoplasm is halted by the epithelial cells. The author attaches much importance to the action of the cilia which, in keeping bacteria on the move, tends to prevent their entrance into the tissues, or compel them to traverse cell surfaces, which either destroy them, or arrange a *modus vivendi* with them. Another physical factor is the limpid serum which, coursing down by gravity, removes bacteria from the danger zone at the cribriform plate. Associated with this factor is that of osmosis. The cilia in the accessory sinuses tend to keep them clear of foreign matter. When they are paralyzed by local inflammation or systemic depression the harmful matter accumulates and furnishes an ideal soil for germ development. The author decries the excessive curetting of these cavity linings which has been practised of recent years. He further expresses the opinion that the sinus suppuration which is found at autopsy in more than one-half of the cases of pneumonia is dependent on a cause it has in common with it, that is, some paresis of the cilia of the air passages, bronchial and sinusoidal, which makes their action physiologically inefficient.

Splenectomy; Five Successful Cases.—W. P. Carr reviews the literature of the surgery of the spleen, and considers that the plan he has followed out in his cases nearly eliminates the chief sources of danger in hemorrhage, shock, and sepsis. He tabulates the indications for splenectomy as follows: (1) Injuries that cannot be safely repaired; (2) all chronic enlargements or hypertrophies of the organ sufficiently great to cause discomfort or produce serious symptoms, except in leukocythemia; (3) benign tumors and cysts that cannot be readily enucleated or removed by partial splenectomy; (4) movable spleen, when enlarged, or causing distress, especially when the pedicle becomes twisted; (5) suppurative splenitis, unless the spleen is adherent to the abdominal wall, so that the abscess may be safely opened; (6) malignant disease or tuberculosis, when primary and confined to the spleen, or when secondary or not confined to the spleen, provided the other parts involved can be also removed or cured. The author considers that an enlarged spleen is not only a menace on account of liability to rupture, but in many cases evidently furnishes an altered secretion which is more or less toxic. Remarkably good, and even brilliant results sometimes follow splenectomy in cases of simple and syphilitic hypertrophy, malarial spleen, Banti's disease, and splenic anemia, while in other cases apparently similar little or no benefit follows. In the present state of our knowledge we cannot always tell certainly which cases will be benefited. In simple hypertrophy and in syphilitic and malarial spleens any symptoms referable to the spleen may be expected to disappear after its removal. Complete cure may be predicted in cases of wandering or dislocated spleen and in splenitis. In any case where diarrhea is severe, cure or great amelioration of this symptom may be expected. The majority of cases of splenic anemia are cured by splenectomy. The detailed histories of the five personal cases are appended.

How Long Shall the Patient Stay in Bed After Abdominal Section?—J. Vance declares that there are many advantages to be gained in getting abdominal patients out of bed as soon as possible. The personal comfort of the patient is greatly increased, the catheter is practically always avoided, and when sitting up they can pass the time agreeably by reading or writing. They eat their meals with a far greater relish than when in bed. Elimination by the bowels, kidneys, and skin are far better, and consequently digestion is greatly aided. With the ability of the intestine to digest comes appetite, strength, and confidence. In the aged all of these advantages are greatly increased. In fact, while younger patients will do well in bed and better out, old patients will not do well at all in bed, and getting them out of bed early becomes, not a procedure of choice, but of necessity. Recumbency for any length of time embarrasses respiration and heart action at any age, but after sixty or sixty-five years of age this embarrassment is so great as to cause hypostatic pneumonia in the majority of patients. By sitting these patients up early the general improvement of metabolism gives to the patient that buoyancy of mental condition which is so very necessary to the successful treatment of the aged. There are no disadvantages to the out of bed treatment, but there are certain dangers, the first and greatest of which is rupture of suture or ligature, causing secondary hemorrhage or the escape of poisonous material into the peritoneum, as, for instance, the slipping of a ligature of an ovarian pedicle or the rupture of a sutured intestine. Those patients best kept in bed are (a) all pelvic cases in which traumatism has been very great and the patient is much weakened by operation; (b) all cases of intestinal surgery in which healing depends to a large extent on absolute quiet of parts; (c) patients greatly emaciated and exhausted by disease prior to operation; (d) cases of profound, acute, or chronic anemia, and (e) neurasthenics, no matter how light the operation. In a word, all patients in whom Nature requires rest and quiet should be bed patients.

Splanchnoptosis from the Standpoint of the Physician.—K. C. Mead discusses this question, notes the great relief of symptoms which follows the reposition of misplaced or prolapsed organs, and figures the Vermehren bandage for general application to this class of cases. Clinically, she has found ptosis of either kidney or stomach, or liver or bowel, in most of the cases suffering from retroversion of the uterus, which, she thinks, goes to prove the hypothesis that enteroptosis is caused by a failure of the supporting ligaments, and that there is seldom to be found simply a ptosis of one organ; therefore, whether the cause is hereditary, constitutional, or due to anemia, overwork, improper dressing, constipation, etc., most of the patients present more or less displacement of the abdominal viscera. Treatment of all such cases must include, of course, regulation of diet and of the normal activity of the gastroenteric tract. The bandage must be carefully fitted to each case with the same care and precision as apparatus is applied in orthopedic practice.

Journal of the American Medical Association, February 23, 1907.

The Factors of Safety in the Organism.—S. J. Meltzer, noticing the tendency of some writers to emphasize the economy of Nature in the animal organism, both as to material and energy, points out that the factor of safety in the body—the surplus above that which is demanded—is far greater than that which is required in artificial structures. For example, he refers to the bilateral organs, each of which is more than capable of supplying the place of both, the kidneys, the ovaries, the thyroids, the adrenals, etc. In the nonpaired organs the same prodigality of tissue and functional capacity is apparent, some organs possess at least twice as much tissue as a maximum of normal activity would require, and in other organs, especially those with an internal secretion, the margin of safety amounts sometimes to ten to fifteen times the actual need. He does not think it probable that tissues are usually inactive, such must be the exception, but they work normally only a fraction of their capacity. The power of self-repair is, moreover, a safety factor far beyond anything in human-made machines. While noting some partial exceptions, the rule seems to be that the organs of the body are built on a plan of a surplus of structure and energy, and Meltzer therefore is inclined to question the theory advanced by some that a minimum, say of proteid ingestion, is the optimum or ideal. There are no facts that support it, and, on the other hand, there are facts that point the other way, such as the abundant secretion of proteolytic enzymes and the excessive capacity of the digestive tract for the absorption of proteids.

These seem to be fair evidence that Nature intended this surplus of material and capacity to be used. The function of supply of tissue and energy by means of proteid food should, he holds, be governed by the same principle of affluence that has controlled the entire construction of the animal for the safety of its life and the perpetuation of its species. In conclusion, he remarks that the factors of safety have an important part in the process of natural selection. The species best provided with a surplus of structure and energy, and thus fitted to meet emergencies, are most likely to survive in the struggle for existence.

The Physiological Conception of Disease in Neurology.—L. Harrison Mettler considers that the anatomical or organic conception of disease, the accounting for disorders by the structural changes found, though still dominant in clinical medicine, is passing, and that the idea that disease is an abnormal physiological process is coming more to the front. In practical scientific medicine it is the abnormal physiology, the disturbed functions, that is the desired goal of study. This is the physiological conception of disease, and while not opposed to the anatomical, on which it in part rests, it is a higher and more accurate conception than the latter. It has, nevertheless, been slow in acceptance, and while recognized by the most advanced leaders of medical thought, it is still inadequately presented in the teaching of the day. It is in neurology, he thinks, that the physiological principle is the interpretation of disease, and its symptomatology is more conspicuous than in any other department of medicine. The neuron theory, which Mettler considers as essentially valid in spite of the modifications necessitated by recent discoveries, has given us one unit, and that a physiological one. In the nervous system it has given us a physiological conception of its diseases, which renders the usual anatomical classifications of the text-books confusing to the average student and practitioner. He gives a summarized explanation of his own tentative physiological classification of nervous diseases, into those of the neuronic or functionating tissues and those of the supporting or nutritional ones, the former being characterized by degenerative, the latter by inflammatory processes, and these again being subdivided. This classification was published several months before the appearance of Grasset's more radical and elaborate presentation of a physiological classification, but Mettler thinks that perhaps at the present time, when the pathology and neurological status of some diseases are still in dispute, a less radical change from the older classifications may have its advantages.

Hysteria in Children.—D'Orsay Hecht says that hysteria in children has not received the attention it deserves, and that its frequency is underestimated. He does not attribute it especially to defective modern methods of education or to a luxurious civilization, since statistics show that it is not confined to those who are specially liable to be affected by such, but is found as often in the children of the poor and ignorant as in those of the rich, and that the major types are recruited more from isolated rural districts than from urban centers. Though too much reverence has perhaps been given to heredity in its etiology, the potential force of direct transmission, he states, must be admitted without reserve. The facts of preceding temporary traumatism in some cases and the impressibility and imitative tendency of children must also be borne in mind. It is useless to look for all the so-called stigmata and accidents of adult hysteria in the child; juvenile hysteria in its objective manifestations is chiefly monosymptomatic, and a single hysterical symptom, standing out in bold relief in the child should, from its very prominence, arouse suspicion as to its functional nature. Motor symptoms prevail; sensory symptoms, according to Hecht, are rarely noted in children, and when they are, are usually of the hyperesthetic type. When an anesthetic zone, suggested or not, appears, it is of the same sharply demarcated, unanatomic type as in adults. Hysterical motor agitation shows itself largely in the form of choreic movements, a variety of facial spasms, convulsive ties and epileptoid seizures. The graver forms of the latter are frequently mistaken for epilepsy, and those of somewhat lesser degree are conveniently evaded with a diagnosis of hysteroepilepsy, a practice to which Hecht objects. As regards diagnosis, Hecht favors the Möbius dictum in dubious cases that "such symptoms may be regarded as hysterical, which cannot be voluntarily produced or which may be simulated." The greatest difficulty is often not so much to avoid mistaking organic disease for hysteria and *vice versa*, as in failing to appreciate that organic disease may, and frequently does, complicate hysteria. We should study the child's temperament, remember its imitative faculty and in all conditions with a prominence of doubtful symptoms, think of hysteria as a not impossible factor. The prognosis is infinitely better than in adults, and, as a rule, the younger the child the better. The fundamental law of treatment is that all hysterical symptoms are psychic, and the means of cure can only be psychic, *i.e.* acting on and through the patient's mind. An early and positive diagnosis favors an early and complete cure. Isolation is imperative when the cordial and efficient cooperation of friends and parents cannot be had. After a cure in isolation has been secured the patients should not be returned too soon to their former associations. Hecht refers with some little detail to Bruns' methods of treatment of these cases, the "method of surprise" and the "method of disregard," and considers the objections that have been made to them rather weak. Unpleasant, and even slightly painful, methods applied with due judgment may be successful because of these qualities in properly selected cases.

The Plague in American Cities.—N. K. Foster remarks that in our intercourse with countries where plague is always in existence, which will increase as our commerce extends, the disease becomes a problem that sanitarians will have to face. Experience in California leads him to the belief that the plague is spread by animals, of which the rat is the chief but not the only one. Circumstances point strongly to squirrels as also disseminating the disease, and he mentions one recent case that is to the point. He believes that the United States Government should investigate this point, as it is of importance to the whole country. While California, from its location, is exposed to the entrance of the infection, he does not think it affords favorable conditions for its spread. The general outdoor life of its people, their excellent physical condition, as a rule, and the good sanitary conditions, will tend to a minimum of cases. Although filth may nourish the germ, we should not depend solely on general sanitary conditions for protection. As rodents carry the disease, they must be particularly watched, and all found dead should be examined. Of the greatest importance, he says, is the early and public recognition of the disease and prompt measures for its suppression.

The Lancet, February 9, 1907

Affections of the Lacrymal Apparatus.—S. Stephenson gives a general description of lacrymal affections, from which a few extracts are herewith made. After a general anatomical consideration of the area involved, he notes the occasional congenital absence of tears and the occurrence of acute inflammation or dacrioadenitis. The latter may terminate in suppuration or resolution. It must be distinguished from erysipelas, purulent ophthalmia, and cellulitis of the orbital tissues. A rare condition is dislocation of the gland, which may be either traumatic or nontraumatic. The lacrymal sac may be the seat of either acute or chronic inflammation, the latter occurring seldom apart from obstruction in the lacrymal passages. The various parts of the lacrymal apparatus are by no means exempt from tuberculosis. Concerning the establishment and maintenance of the patency of the duct, the author notes the disappointing results of probing and the excellent results following the exturpation of the lacrymal sac, though the author does not regard the operation as an easy one. He thinks it may be properly recommended under the following conditions: (1) When ordinary methods have failed, or cannot be applied owing to the particular circumstances of the case; (2) when there is a definite and pronounced distention of the sac, or when fistulæ are present; (3) when tuberculosis of the sac exists; (4) when a cutting operation on the eyeball, as cataract extraction, is imminent, and (5) when a septic ulcer of the cornea coincides with a diseased condition of the lacrymal sac. It might be expected that epiphora would continue after excision of the sac but, as a matter of fact, the removal of a source of reflex irritation appears to reduce the secretion from the lacrymal gland to a minimum.

Appendicitis in Typhoid Fever.—C. I. Green states that typhoid fever may give rise to appendicitis in one of two ways. First, a true typhoid inflammation and ulceration, possibly going on to perforation, may affect the lymphoid tissue of the appendix just as it may any other portion of the intestinal tract, and, secondly, appendicitis may develop in a patient suffering from typhoid fever in consequence of a general edema and hyperemia of the gut. For it must be obvious that during the course of the typhoid fever the whole of the gut which is affected by the typhoid inflammation, viz., the lower part of the small and the first portion of the large, is in a generally congested and hyperemic state; and the appendix, from its situation in the midst of this disturbance, must of necessity participate in the general congestion and edema. But any congestion of the walls of the appendix, especially when associated, as it would be in this case, with a greatly increased glandular activity, must run the risk of obstructing the narrow outlet of that organ and setting up an intense local inflammation there. The likelihood of serious trouble arising in this way would naturally be greatly increased should the appendix

be stenosed, kinked, or bound down by adhesions the result of previous inflammation. There can be no doubt that the conditions brought about by typhoid fever are those likely to rouse into activity a latent or chronic appendicitis. Three successful cases all coming to operation for the appendicitis are narrated, and the author quotes freely from the literature of this association of pathological processes. He says that there is not likely to be much difference of opinion as to the advisability of operative interference in those cases where the extent to which the appendix is involved can be assumed from the general symptoms, for it is obvious that if an operation can be avoided or postponed it is better to do so; the typhoid fever patient already has enough to tax his strength without a laparotomy being added. Therefore, so long as there is no reason to believe that either gangrene or perforation of the appendix has taken place a strictly conservative policy is indicated. But should the symptoms point to perforation, then an immediate operation is necessary. A simple appendectomy in the early stages of typhoid fever has usually a favorable prognosis, but when it has to be undertaken in the third or fourth week of the disease the cases recorded show the heavy mortality that one would expect. Even those operations, which in themselves are comparatively slight, have a high mortality when the patient is exhausted by the typhoid fever.

Sanitary Conditions in Relation to Infantile Mortality.—The observations of T. Devine are applied to England, but are nevertheless of interest. He advances the following propositions: (1) The infantile mortality of rural England is lower than that of urban England. (2) Taking things as they are in England and Wales, it must be remembered that a considerable proportion of infants are hand-fed. This opens up the way, so to speak, for the play of insanitary conditions through the influence of food. Fatal diarrhea in hand-fed children is, on this account, probably proportionate to the degree of insanitation to which the infant is exposed. Infantile diarrhea is twice as fatal in towns as in the country. (3) Measles is a very fatal disease among young infants, and it is especially so among those living under insanitary conditions. Deficient ventilation, in particular, tends to a fatal issue. It is much more fatal in towns than in the country. Whooping-cough is less influenced by the same conditions, and hence its fatality in towns is less marked. (4) It can hardly be contended that an infant brought up in the dark, damp, congested areas of slums has not less resistant power than one brought up under more sanitary conditions. If it has less resistant power it must more readily fall a victim to disease. (5) The influence of general insanitary conditions as they affect great towns may be measured by one or another of three death-rates at all ages, and the corresponding infantile mortality may be studied. These rates are: (1) the pulmonary tuberculosis death-rate; (2) the diarrhea death-rate, and (3) the "fever" death-rate. (6) The factor "overcrowding" includes many conditions which must be classed as insanitary, as pollution of air, water, soil, etc., and overcrowding has been proven to conduce to a high infant mortality rate.

Continuous Use of Oxygen in a Case of Bronchopneumonia in a Cardiac Subject.—The noteworthy features in the case reported by B. E. Myers are (1) that a person, aged sixty-two years, with old heart trouble, recovered from a severe attack of bronchopneumonia; (2) the excellent effects in this instance of the continuous use of oxygen for a long period, and (3) the apparent benefit of strychnine in Cheyne-Stokes breathing. In the course of the treatment oxygen was given continuously for a period of 110 hours. The patient's temperature became normal on the ninth day, and he made an uninterrupted recovery.

British Medical Journal, February 9, 1907.

Influenza and Epistaxis.—Three cases of influenza in children, all in the same family, are reported by H. S. Brown. The interesting feature of them was that all were accompanied by epistaxis, varying in direct proportion to the apparent strength of the invasion, and occurring at the time of the subsidence of the temperature to normal. Not one of the children remembered a previous attack, and their mother confirmed this. Quinine had been given during the influenza, and the author suggests that the bleeding may have been an idiosyncrasy with this remedy. Another suggestion is that the bleeding pointed to a local invasion of the nasal mucosa by the influenza toxin.

A Pair of Forceps in the Abdominal Cavity for Ten Years.—While examining a patient, J. E. F. Stewart detected by abdominal palpation a body suggestive of a pair of scissors in the region, and learned that the patient had been operated on over ten years previously for an ovarian tumor. X-ray examination confirmed his suspicion and the abdomen was opened. Artery forceps were found of the length of nearly five inches with a handle breadth of nearly two inches. During this long interval she had had attacks of sudden acute pain, constipation alternating with diarrhea, and pains in the lower limbs. The forceps were found inside the lumen of the bowel. What at first appeared to be a cicatricial band between the rings of the handles kept the forceps in place, and capable only of moving with the portion of the bowel, into which they had got. The author incised the gut, and, owing to the patient's condition, had rather hastily to remove the forceps, when he found that the supposed cicatricial band was the point of anastomosis of two loops of bowel which had been caught between the handles of the forceps, and thus caused a "short circuit" between two points, about 12 inches apart.

The Temperature in Malignant Disease of the Liver and Bile Passages.—J. W. Russell reports on this fact in fifty-two cases of malignant disease, in thirteen of which the growth certainly arose from the gall-bladder or bile ducts. His general conclusion, summarized from a study of the temperature charts he presents, are as follows: Nearly two-thirds of the cases of malignant disease of the liver show some degree of pyrexia, at any rate in their later stages. The pyrexia is capable of attaining a considerable height, but rarely shows genuine intermissions, in the sense of subsidence of the morning temperature below the normal level. It is not uncommon to observe successive periods of fever alternating with apyrexial intervals, and sometimes these alternations may occur with great regularity. Rigors do not occur in uncomplicated cases of growth of the liver. Pyrexia seems to occur in a still larger proportion of cases of growth of the gall-bladder and bile ducts being recorded in more than three-quarters of the cases investigated. The condition is frequently complicated by the presence of gallstones, and it may be due to this fact that the pyrexia often reaches a greater height, with larger excursions, than is seen in the growth of the liver itself. Rigor apparently occur only when gallstones are present. An isolated high rise of temperature may, however, be observed in growth of the bile ducts in the absence of gallstones, but as a rule such a rise is suggestive of the presence of gallstones. The three cases of combined growth and suppuration do not present anything in the temperature charts to strongly suggest the presence of pus, though one case gave a single high rise of temperature. In hepatic abscess the charts may present little that is characteristic of suppuration, at any rate if observed only for a short time; but where high rises of temperature from a low level are noted these are likely to be repeated at frequent intervals, and thus to contrast with the isolated rises seen in cases of stones or growth. It is possible, however, that the examination of a larger number of cases might not support this statement.

The Dissemination of Intraabdominal Malignant Disease by Means of the Lymphatics and Thoracic Duct.—This subject is considered by W. M. Stevens, who summarizes the histories of several cases and presents two diagrams illustrative of points in his main argument. His concluding observations, which sum up his various contentions, are as follows: (1) The thoracic duct undoubtedly plays an important rôle in the dissemination of intraabdominal malignant disease and of tuberculosis. This duct may act as a "simple carrier" of infective material, or it may be directly involved, and in some cases it may be actually obstructed. In connection with blocking of this duct, it is very remarkable that chylous ascites is so rare and also that dilatation of other lymphatic channels can so seldom be demonstrated. (2) The supraclavicular glands on the left side are more frequently involved in abdominal malignant disease than is generally supposed, and in many cases careful percussion will show the presence of glandular enlargement in the clavicular and infraclavicular regions, and may even thus give a clue to the nature of the abdominal affection. It is possible that these glands become infected through "regurgitation," but a more likely method of infection, and one which can be demonstrated in some cases is by direct communication of the disease along the walls of the thoracic duct, extending to the lymphatic vessel coming from these glands. The right clavicular glands are very seldom involved, and the reason for this is fairly obvious on studying the lymphatic anatomy. (3) The possible mode of infection of other parts—chest, liver, inguinal glands, abdominal wall, etc.—have been discussed. (4) It is probable that many cases of so-called primary mediastinal growths may really be of secondary origin, since it is well known that cancerous disease, especially of the stomach, may be very "latent," and, moreover, a small growth of the stomach, though it has been the cause of marked secondary growths, may even be overlooked at the autopsy unless especial care be taken.

The Claim of the Surgeon to Conduct the After-Treatment of Operative Cases.—This claim is maintained by C. A. Morton, who says that the only reasonable

view of the matter is that the medical practitioner who has been in charge of the case up to the time the operation is performed should hand over the treatment entirely to the surgeon who has taken the responsibility of operating, for the success or failure of an operation may, to a large extent, depend on the after-treatment. This is practically what is done in hospital service when a case is transferred from the medical to the surgical service. The author then goes on to make some observations on the position of the patient after operation and on flatulent distention after abdominal operation. Concerning the former, he says that in all cases in which the drainage of any quantity of fluid from the abdomen is desired, the patient should be kept in the half-sitting position—that is, with his chest well propped up on pillows. This is of the greatest importance in acute suppuration in the abdomen, especially when diffused, as in peritonitis. It has been strongly advocated in such cases by some of the American surgeons, and is sometimes spoken of as Fowler's position. In suppurating appendicitis not only must the chest and upper abdomen be raised higher than the lower abdomen, but the left side of the abdomen must also be propped up on pillows, so that the right lower abdomen, from which the drainage tube will protrude, is the lowest part of the abdominal cavity, except the true pelvis. In order to judge if his patient is at a right slope, it is necessary to inspect the abdomen (of course covered with the dressing) after or during the adjustment of the pillows or bed-rest. We must not be content with the apparent position of the abdomen from inspection of the patient covered with the bed-clothes. We should not leave the arrangement of the position of the patient to the nurse, unless we feel sure she knows exactly how to place the patient, from her experience in other cases. Concerning the matter of flatulent distention, the author says that his chief reliance for its removal is very hot turpentine enemata repeated every few hours, and given with a soft rubber tube, left in the rectum for a short time after, to allow any gas which reaches the rectum to readily escape through the sphincter. They should be as hot at the moment they are given as the nurse can bear her hand in, and the turpentine should be most thoroughly made into an emulsion with soap and a pint of hot water, and, if one pint fails, two or three pints very slowly introduced by a funnel and small rubber tube, with the pelvis elevated, may succeed. We may give a few grains of calomel, followed by a Seidlitz powder, as well, and repeat it. There is no doubt that in many cases in which tympanitic distention is marked and vomiting frequent, and the patient seems really very ill, this line of treatment will, if persisted in, remove the alarming symptoms. Possibly the frequent hypodermic injection of strychnine may help somewhat. Morphine must be avoided. Pain is not usually a marked feature in this condition, and morphine will tend to paralyze the bowel. And it is no use putting nourishment, even though it is liquid and peptonized, into the patient's stomach in such cases. We must so arrange the time of the hot turpentine enemata that nutrients can be retained for some hours.

Berliner klinische Wochenschrift, February 4, 1907.

Juvenile Physiological Albuminuria.—Ullmann examined the urine of forty-two small children and school girls between the ages of two and a half and thirteen years. These children were supposed to be perfectly healthy, and for the most part were well nourished, and all were subjectively well. Fourteen, or 33.3 per cent., however, had albumin in their urine without any other evidences of nephritis, and on the basis of this experience Ullmann suggests that this condition must be considered as a more or less physiological manifestation of early life. In most instances the tendency is outgrown, but when it is found in adults it must be regarded as the persistence of this early condition. He therefore does not agree with Leube in regarding the albuminuria of puberty of this author as a disease of development with a well characterized clinical picture, and also does not consider that it should be called orthotic albuminuria, but rather that the condition should receive the name of juvenile physiological albuminuria, and be differentiated as such. This diagnosis naturally can be made only after long-continued and careful observation. Treatment is superfluous, for in most cases the tendency disappears as the individual grows up, and in the others it persists in spite of all therapeutic efforts. It is without effect on the patient's health or length of life, and its presence need not be apprehended by insurance examiners.

Milk Infection as a Cause of Primary Intestinal Tuberculosis in Children.—Fibiger and Jensen report at great length two cases of intestinal tuberculosis in infants which were undoubtedly the result of infection through milk taken from tuberculous cows. The authors point out that there is now no longer any doubt that the tuberculosis of cattle can produce the disease in man, and that the danger from this source must be guarded against by rigid surveillance of dairy products. Most cases of human tuberculosis are the result of infection from other human beings, but for infants milk infections are of the greatest importance. Hospital records are demonstrating that the frequency of mesenteric tuberculosis in infants is much greater than has been supposed, and it must not be forgotten that the number of cases in which the infection originated in this way is much larger than the post-mortem records show, because the disease frequently produces widespread lesions in other organs, so that it is no longer possible to demonstrate the site of the original infection. There is, therefore, no doubt that the consumption of raw milk is an important source of tuberculous infection in infancy.

Münchener medizinische Wochenschrift, January 22 and 29, 1907.

The Pathology of Appendicitis.—Flesch is inclined to doubt the belief that the appendix is a rudimentary organ or one in the course of retrograde metamorphosis, and suggests that it is possible to attribute to it a useful function. He regards it as a glandular structure placed in the region of the ileocecal valve for the purpose of in some way modifying the conditions existing in this portion of the large intestine where a pronounced change in the character of the intestinal contents and in the direction of their movement takes place. The inflammatory processes that occur in the appendix may be compared to those observed in other glandular organs, and are the result of bacterial infection following local injury or irritation through mechanical or chemical causes. The greater frequency of the disease in certain families indicates that through some inherited peculiarities of structure inflammatory changes are predisposed to, but the inciting cause is a purely individual one. Constipation, which appears to be on the increase among all classes of society, is to be considered as an important factor, and the prophylaxis of the disease demands concerted efforts to combat this tendency by suitable modifications of diet and mode of life.

Scopolamine Anesthesia in Obstetric Practice.—Three articles on this subject are presented. The first of these is by Gauss and is devoted to a consideration of the results obtained in 1,000 confinement cases conducted under this form of anesthesia. Gauss is a very ardent advocate of the method and ascribes the less favorable opinions of other authors to the fact that their technique was lacking, or the preparation used was unreliable. In his series of 1,000 cases the maternal mortality was zero as far as the anesthesia went, and in all other respects the method was equally satisfactory. No undesirable effect on the duration of the labor, on postpartum hemorrhage, or on the welfare of the infants was observed, and the author considers that under conditions which permit sufficiently careful observation of each patient the method is a highly satisfactory one. Whether it is desirable for use in large institutions, or in general practice, is still a question, as the dosage must be controlled by a careful observation of the patient's perceptive faculties, which naturally demands a great deal of close attention.

Preller, in the second communication, also expresses himself favorably in regard to the scopolamine-morphine method, though with somewhat more reserve than Gauss. Out of 120 cases of this sort, in 70 per cent. the anesthesia was successful, in 18 per cent. it was for the most part satisfactory, and in 12 per cent. the effect was poor, principally because the injections were made too late. In 20 to 25 per cent. of the cases impairment of the heart's action was noted, and in about the same proportion of cases the duration of the labor appeared to have been protracted. Twice symptoms of poisoning, accompanied by hallucinations, were noted. The author, therefore, concludes that this method of anesthesia will probably be restricted to hospital work, where physicians and trained attendants are constantly at hand. Before attempting to use the method in private work the practitioner should have familiarized himself with the properties of the combination through extensive hospital experience, and he will have to devote to his patient the necessary time for careful supervision of the period of anesthesia.

Penkert, in the third paper dealing with this subject, describes a combination of morphine-scopolamine anesthesia with spinal anesthesia. A special technique for performing the injection into the spinal canal is detailed, and the author expresses the opinion that this method forms the most humane type of anesthesia for abdominal and gynecological operations.

Book Reviews.

LECTURES FOR NURSES. Jamestown, N. Y.: The Chautauqua School of Nursing. 1906.

UNDER the above title there has been received a book which purports to give a course in general nursing, apparently on the plan of the "correspondence school." The perusal of its pages is intended to furnish the candidate with a knowledge of what has now come to be regarded as a profession, but we think that knowledge gained in this manner will hardly fit a nurse for the duties she is compelled to perform, and if such knowledge be the limit of her qualifications, few physicians would care to take the risk of employing her. Practical hospital experience constitutes the *sine qua non* of nursing, and nothing can be substituted for it. As a supplement to the practical knowledge obtained in hospital work, the lectures here presented would be very useful, for they are well written and calculated to impart sound information in an easily assimilable form. But book teaching without practical training, in nursing as in medicine, gives only the "little learning" which high authority tells us is a dangerous thing.

A PRACTICAL TREATISE ON MATERIA MEDICA AND THERAPEUTICS, with Especial Reference to the Clinical Application of Drugs. By JOHN V. SHOEMAKER, M.D., LL.D., Professor of Materia Medica, Pharmacology, Therapeutics, and Clinical Professor of Diseases of the Skin in the Medico-Chirurgical College of Philadelphia; Physician to the Medico-Chirurgical Hospital; Member of the American Medical Association and the British Medical Association; Fellow of the Medical Society of London, etc., etc. Sixth Edition. Thoroughly Revised. (In Conformity with Latest Revised U. S. Pharmacopœia, 1905.) Philadelphia: F. A. Davis Co., 1906.

IN this new edition the author has added a section on pharmacy and pharmacology, with a classification of remedies, a table of poisons and their antidotes, and directions for prescription writing. The second section, dealing with medicinal agents, such changes as were necessary to make the work conform with the latest edition of the U. S. Pharmacopœia have been made. Part III. is devoted to a consideration of the non-medicinal therapeutic agents—to electrotherapy, kinesitherapy, pneumotherapy, hydrotherapy, psychotherapy, radiotherapy, actinotherapy, musicotherapy, dietetic treatment, etc. Shoemaker's Therapeutics has long enjoyed a well-deserved popularity, and has ranked among the best of the works of the kind published in this country. This new edition can but add to the measure of appreciation of the work.

THE BACTERIOLOGICAL EXAMINATION OF WATER SUPPLIES. By WILLIAM G. SAVAGE, B.Sc., M.D., D.P.H. Medical Officer of Health, and Public Analyst, Colchester, etc. London: H. K. Lewis, 1906.

THE size of this book precludes an exhaustive presentation of the matter with which it deals. It makes no pretense of bringing much that is original, nor does it depart from the general plan upon which books of this sort are generally written. Within the space allotted, however, the little work is exact and up to date. The chapters on the colon and typhoid groups are excellent summaries of these difficult subjects. Too little space is given to the streptococcus group, though this is excusable by reason of the confusion in which this variety of organisms still finds itself. Throughout the book, however, the most recent researches and methods have been utilized; though in many places they cannot be more than indicated. A gratifying feature, all too rarely found in writings published in foreign countries, is a thorough acquaintance with the work of American scholars. The tone of the book is critical and unwarranted conclusions are avoided throughout. For this reason, if for no other, the little treatise is well worth reading and constitutes a valuable addition to the literature of the subject.

VOICE PRODUCTION IN SINGING AND SPEAKING, based on Scientific Principles, by WESLEY MILLS, M.A., M.D., etc., Professor of Physiology in McGill University, and Lecturer on Vocal Physiology and Hygiene in the McGill University Conservatorium of Music. Philadelphia and London: J. B. Lippincott Co., 1906.

THIS book is written by one who is at the same time an eminent authority in his special field of medicine and a trained musician. His preface informs us that his purpose has not been to write an exhaustive work on vocal physiology, but to keep in mind, as he has penned his chapters, the real needs of the practical voice user, and to give him a sure foundation for the principles that must underlie sound practice. The consequence is that his pages are attractive to the laryngologist, who sees in them sound, common sense, and attractive also to the singer, who receives much valuable information. He considers the lack of good actors and singers of the present day, as compared with former times, due to the fact that we do not to-day pursue right methods for a sufficient length of time. Especially is this true with reference to breath control. "In this alone singers to-day are far behind those of the old Italian period, not because they do not know how to breathe, but because they are often unwilling to give the time necessary for the full development of adequate breathing power and control." In other words, singers are apt to fall into the "rush" methods which have come to be characteristic of the present age in almost every line of endeavor. The book is well illustrated and well printed. As is usually the case with such a technical subject, there are here and there statements with which perhaps not every teacher of singing would agree, but the range of topics considered is wide, their exposition is lucid, and the advice given to voice users is intensely practical.

PRACTICAL DIETETICS, with Reference to Diet in Disease. By ALIDA FRANCES PATTEE, Graduate, Boston Normal School of Household Arts. Late Instructor in Dietetics, Bellevue Training School for Nurses, Bellevue Hospital, New York City. Special Lecturer at Bellevue, Mount Sinai, Hahnemann, and the Flower Hospital Training Schools for Nurses, New York City; St. Vincent de Paul Hospital, Brockville, Ontario, Canada. Fourth Edition. New York: A. F. Pattee.

THIS is intended primarily as a dietetic guide to the sick, but it is an excellent cook-book for those in health as well. The first part contains a general disquisition on food and food values, general rules for feeding the sick, directions for serving, and a brief chapter on measurements, in which is a useful table of the equivalents of the saltspoon, teaspoon, tablespoon, cup, and other domestic units of measure. The second part contains numerous recipes for the drinks (soft), soups, meats, bread, and sweets, which may be needed for the sick and those with delicate appetites that require coaxing. These recipes are excellent, and could be used by any plain cook or housewife, with gratification to the master of the house. The only criticism we have to offer is that the author almost always specifies some particular make of olive oil, chocolate, grape juice, etc. If there were but one make that could be relied upon this might be necessary, but where there are many of each of these just as good and honestly made as those mentioned, the specific designation smacks a little of the advertisement. The third part is devoted to a combination of the foods and special diets called for in individual diseases. In this the physician will find many hints enabling him to prescribe the appropriate diet without wearying his patient with the monotony of milk and beef broth. Nurses will also find much that is helpful in the book, and many a patient, wanting something, yet not knowing what he wants, will thank the author for the suggestion of a dainty dish.

GENITOURINARY DISEASES AND SYPHILIS. By HENRY H. MORTON, M.D., Clinical Professor of Genitourinary Diseases in the Long Island College Hospital, etc. Second Edition. Revised and Enlarged. Philadelphia: F. A. Davis Co., 1906.

THE second edition of this book was made necessary by the numerous changes and advancements which have been made in this subject within recent years, chief among which are the developments in the surgery of the prostate and the kidney. In the treatment of gonorrhea the author favors the methods used by the Berlin school of investigators, whose opinions are also largely quoted throughout the book. The chapters on syphilis are very satisfactory, presenting the subject in a concise, yet sufficiently complete manner to afford to the student a very comprehensive idea of this important subject. The book, although by no means a manual, presents in a sufficiently complete manner the modern status of genitourinary surgery.

DIE THERAPIE DER HAUT UND GESCHLECHTSKRANKHEITEN. Für praktische Aerzte; von Dr. REINHOLD LEDERMANN, Specialarzt für Hautkrankheiten in Berlin. Dritte durchgesehene und erweiterte Auflage des Therapeutischen Vademekum der Haut und Geschlechtskrankheiten. Berlin: Verlag von Oscar Coblentz, 1907.

THE changes from the previous edition consist in the addition of paragraphs on treatment by means of light and other forms of radiant energy, by cold, and by local hyperemia, and in the addition of most of the newer remedies used in these classes of disease. In his judgment of the various methods the author is quite fair and impartial. But the *x*-ray treatment of tinea tonsurans, now generally accepted as altogether the most efficacious, is barely mentioned, and is recommended only for severe cases, while the treatment of lupus erythematosus by the high frequency current is omitted altogether. Contrary to the general belief in this country, electrolysis is placed ahead of the electrocautery in the treatment of nævus vasculosus. The characteristics of the book have not been altered with its change of name: it is still chiefly a collection of valuable formulæ and therapeutic hints, with enough text to bind the whole together.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Regular Meeting, Held February 7, 1907.

THE PRESIDENT, DR. JOHN A. WYETH, IN THE CHAIR.

Regulations Endorsing State Law to Regulate the Practice of Midwifery.—The resolution was offered, seconded, and unanimously carried that midwives should be regulated and supervised by competent authorities. The resolution favored the enactment of a State law to regulate midwifery and to provide for examination for licenses following the precedent set by States in the Union, by Germany, and other countries. This resolution advising or indorsing the enactment of a State law was presented to the Council and was accepted by the Council and recommended to the Academy of Medicine for its concurrence.

The Bacteriology of Influenza.—Dr. MARTHA WOLLSTEIN read this paper. She said that the organism which was present in such large numbers in the sputum of influenza patients was one of the smallest known. It was two or three times as long as wide, with rounded ends, sometimes forming threads, Gram negative, and non-motile. No spores were formed and the organism was strictly aërobic. It grew only upon media containing hemoglobin. The colonies were small and dewy in appearance, colorless and transparent, and showed little tendency to become confluent. The bacillus grew between 42° and 26° C., and therefore in this climate the temperature was too low to permit its flourishing outside the body. An exposure to 43° C. for a few hours killed it. Pfeiffer's experiments proved that it quickly died in water and that in sputum the bacilli were probably alive and infectious for fourteen days, if protected from drying. Development outside the body in water or soil was not possible; the spread of influenza by means of dried sputum particles was possible only to a minimum degree, and contagion took place, as a rule, by means of fresh particles of moist nasal or bronchial secretion. The bacilli were present in large numbers in the sputum in the early stage of the disease. The influenza bacillus had a special predilection for the mucous membranes of the respiratory tract, and usually entered the body through them, attacking, as a primary point of infection, the nose, nostrils, larynx, bronchi, or lungs. Hence the necessity of disinfecting all linen and all eating utensils used by the patient. More rarely the eye might be involved first. The involvement of the ear was always secondary. The bacillus of influenza was a facultative pus producer, and suppurative inflammation of the serous membranes had been reported. The bacillus had never been demonstrated in the digestive tract. It had been demonstrated in the blood of living adults in two cases only. In her experience the influenza bacillus was not found in the throats of healthy children nor in the throats of children in whom lesions of the respiratory tract did not exist. Rabbits were rarely killed by one inoculation of influenza bacillus, either intraperitoneally or subcutaneously; but they bore repeated inoculations badly, becoming emaciated and very weak. The blood of influenza patients agglutinated influenza bacilli in low dilutions and rarely in the early days of the disease. The absence of agglutination with the serum from cases of acute influenza was to be explained probably by the fact that the agglutinins develop slowly. Rabbits required many inoculations before the agglutinins began to appear. Thus far all attempts to produce an active immunization to the toxins of influenzal bacillus had failed.

Dr. WM. HALLOCK PARK said that Dr. Wollstein had done a great deal in the study of the bacteriology of influenza and, therefore, he hesitated in entering upon a discussion with her. He spoke of the diagnostic import of finding the influenza bacillus, personally he did not think it amounted to much unless the symptoms of the disease were present. In cases of suspected influenza bacterial cultures gave little aid in the diagnosis or the treatment. If the symptoms were not striking and characteristic, the finding of the influenza bacillus did not suggest much, as there were many differences in virulence of different strains, and cultures showed nothing concerning virulence. Mixed infection was always present and often most important. In bronchopneumonia at present the pneumococci gave similar symptoms. During the pandemic the cases presented markedly typical symptoms; but in the years between these striking symptoms were not shown. In the Adirondacks the presence of influenza bacillus was studied in those living there; in nearly all the tuberculous cases this bacillus was found. The influenza bacillus was like the pneumococcus in many things. It caused meningitis and cerebrospinal meningitis in not a few cases.

Influenza in General Practice.—Dr. W. H. KATZENBACH said that influenza was an acute infectious and contagious disease caused by the Pfeiffer bacillus. This bacillus was found in all cases of uncomplicated influenza in the nasal and bronchial secretions in almost pure culture, and in the bronchial tubes and lungs in the pulmonic complications. It disappeared with convalescence. Epidemics had been frequent since the fourteenth century, the first one that was carefully described being in 1577. Since the pandemic of 1889-1890 the disease had occurred in epidemic waves in this and other cities. But in the intervals of the epidemics sporadic cases had been frequently observed at all seasons, which in every respect resembled those of the epidemic. The account of the rapidity with which the infection was carried in epidemic seasons made it appear that the bacillus was air-borne and entered the human subject through the inspired air. During an epidemic influenza attacked all classes and all ages, though the young were less susceptible. No one could consider himself immune. Relapses were frequent, and one attack did not confer immunity against others. The period of incubation was from one to three or four days. In all epidemics the local symptoms were so varied that although attempts had been made by most authors to group the disease into several clinical types, yet one or more of these types frequently existed in combination. After describing the symptoms, diagnosis, and prognosis of these various types of influenza, he took up a consideration of the treatment. During the prevalence of an epidemic of influenza, the old, the chronically feeble, and those suffering with cardiac, pulmonary, or nephritic troubles should be guarded against any and all depressing influences. The patient should be isolated, and confined to bed in a warm and well ventilated room and protected from draughts. He should be kept at rest and in quiet, and visits of friends and relatives should be prohibited. The nasal and bronchial secretions should be disinfected. The indications were to control the pain, quiet the cough, control the fever, maintain nutrition, eliminate the toxins, and induce sleep. The treatment might be begun with a dose of calomel and saline unless contraindicated. If pain was severe and nausea was present a moderate dose of morphine would relieve, given under the skin. A single dose of phenacetin with codeine would quiet the cough, relieve the pain, reduce the temperature, and induce sleep. This might be followed by one of the alkaline salts. Alkaline waters should be freely given. Antipyretics should be avoided, except possibly a moderate dose at the beginning. If the temperature was high and delirium present, a cool pack was of value. If the temperature was moderate and the skin moist, baths could be dispensed with. While fever was present milk and vichy, buttermilk, kumys, or zoolak in small quantities, and if tolerated eggnog, later eggs, raw or cooked, and during convalescence scraped

beef, chicken, beefsteak, chops, green vegetables, bread and butter might be given. Convalescence was often protracted and was frequently characterized by nervousness, insomnia, anorexia, vasomotor, or cardiac weakness.

Dr. Morris Manges believed that we underestimated the ultimate mortality in influenza. Very little care was given by physicians to prevent the spread of this disease, and the more polite use of handkerchiefs should be asked for. The disease was carried largely in the moist secretions from the mouth. A diagnostic point which he considered of importance was the sticky râles heard at the base of the lungs; these râles he believed to be quite characteristic of the disease. They were rather loud, bubbling râles and sticky in character. Therefore, when ever in doubt as to the existence of this affection he said that we should search for these râles at the base of the lungs and posteriorly. Dr. Manges said that he knew of few problems in diagnosis more difficult than differentiating a case of grippe from the early stages of typhoid fever. This was especially so as the rash occurs in grippe more often than usually taught. In a large number of cases albumin was present in the urine and this persisted for a longer or shorter period of time This had been considered by the various insurance companies.

Influenza in Its Relation to Diseases of the Nervous System.—Dr. Joseph Collins read this paper (See page 337).

Dr. B. Sachs said that any one who had had experience in studying diseases of the nervous system knew that the influence of influenza in them had been greatly overestimated, and so far as his own experience was concerned he had yet to see a single case in which a nervous disease could be positively established as being due to the influence of the Pfeiffer bacillus. A recent experience helped to indorse this view. A child was supposed to have an influenzal meningitis. A lumbar puncture was done and the meningococcus found, thus disproving the influenzal nature of it. In all probability there were cases of meningitis due to the influenza bacillus, presenting all the signs of a basilar meningitis, the entire course of the disease being milder than they were accustomed to see in a tubercular meningitis, and the disease ending in recovery. In speaking of the nervous symptoms due to the influenza bacillus one should bear in mind the persistent headache and insomnia, the former largely due to a subacute meningitis due to the influenza bacillus, the latter due to the active hyperemia in all probability. Myelitis and neuritis due to the influenza bacillus were rarely met with, although it was extremely difficult to prove. In myelitis a diagnostic point was the repeated attacks and rapid recovery.

Influenza in Children.—Dr. Henry Dwight Chapin said that the difficulty of recognizing influenza in children depended upon two factors, whether the disease was prevalent or not, and the age of the patient. Young children did not seem to be so susceptible to the disease as adults. The fact that influenza might take on a grave form or be followed by serious sequellæ emphasized the importance of an early diagnosis. The younger the child the more severe usually was the infection. Catarrhal disturbances of the respiratory tract predominated in children, and were more virulent than the ordinary inflammations met with in this region. This was not only seen locally, but in the disposition of the catarrhal process to extend downward. In some ways this was analogous to the course in measles. The larynx, trachea, and bronchi were quickly involved, but, in many cases, the inflammation did not extend below the larger or median sized tubes. In others there was an involvement of the small tubes and alveoli coming on soon after the onset of the disease. This type of bronchopneumonia was much like the ordinary form so far as the physical signs were concerned, but early prostration was more marked, and the temperature was usually irregular and higher than the local lesion would seem to warrant. True lobar pneumonia was also not infrequently seen and, as in other influenzal conditions, exhibited disturbances of temperature and circulatory and nervous depression out of proportion to what would be expected from the pulmonary signs. Perhaps the most frequent exhibition of pneumonia was seen in the form of irregular patches with sneaking invasion and where it was very difficult to decide whether the process was catarrhal, croupous, or both. Various grades of pleurisy were frequent accompaniments of all the forms of pneumonia, and empyema might be the terminal condition. The latter was even more insidious than usual, especially in infants, and Dr. Chapin had seen more of this disease in the past two months than usual. In cases where the gastrointestinal disturbances predominated there might be severe vomiting and the passage of loose, undigested stools, which later might contain mucus and even blood. The cases in which pure nervous disturbances predominated over the catarrhal symptoms did not seem to be so common in early life. Some severe cases might start with convulsions and simulate meningitis, with photophobia, stupor, and, in older children, headache and delirium. In influenza the fever was apt to be irregular and at times very high, especially in young infants. In some cases fever and prostration with little evidence of any local inflammation would be the principal symptoms. In other cases an irregular fever might last for several days and simulate typhoid fever. The skin was sometimes covered with various forms of erythema, which might at times simulate measles or appear in scarlet form. The urine frequently showed traces of albumin. In diagnosing influenza the bacteriological aid was not as great in practice as it was in theory. The bacilli were difficult to discover and frequently disappeared early in the disease. In the great majority of the cases the physicians must depend entirely on clinical signs for a diagnosis. In some cases he must depend largely on a process of exclusion. The disease was highly contagious.

Dr. L. Emmett Holt said that influenza was highly contagious, and in the family the adults were apt to be first infected and the children secondarily. He had seen several cases of influenza occurring in young children, the disease having been caught from the nurse. The general practitioner did not sufficiently take into consideration the importance of isolating nurses who had the care of young children. The catarrhal cold was a menace to the child with whom the nurse lived constantly. It was impossible to differentiate the ordinary catarrhal colds from those due to the influenza bacillus. Therefore, it was better to isolate half a dozen cases of ordinary colds than to run the chance of exposing the young to one case of influenza. In most cases of influenza he had seen the temperature was out of proportion to the other symptoms. If the temperature ranged up to 102°, 105°, or even 106°, with very few local symptoms, or none at all, he always looked upon a diagnosis of influenza as the most probable. Cases of persistent temperature with a little ear trouble, the temperature going up because of the influence of the influenza bacillus, and not because of the ear trouble, were very important from the standpoint of the otologist. Such a temperature continuing called for a mastoid operation. Cases of uncomplicated influenza might run high temperatures for days, and he had seen cases with fever continuing for five or six days, the temperature being disproportional to the other symptoms.

Some of the Lesions of the Middle Ear Due to Influenza.—Dr. Gorham Bacon said that at the New York Eye and Ear Infirmary there had been, in 1897, 161 mastoid operations; in 1889 the number had rapidly increased, while in 1905 there had been 555 operations. Influenza played an important part in the acute inflammations of the middle ear, and children were more frequently affected than adults. The pain was slight even in the severer cases. The sticky

sanguinolent purulent discharge was quite characteristic in children, and in examining the pus or serum, one found usually a mixed infection. The staphylococcus might be the cause of the severe inflammation. After incising the drum membrane the temperature usually fell, the discharge became purulent, and the disease ran a course of from ten days to three weeks, the temperature ranging from 101° to 105°. It was in this class of cases that the otologist should exercise great care, and if a simple bronchitis was present, it was not wise to administer an anesthetic for fear of setting up a pneumonia. Incise the drum membrane without a general anesthetic; but if it was absolutely necessary to use one, he advised chloroform. After incising the drum head the high temperature might be due to mastoid involvement, or to a deep-seated pneumonia. The knowledge of the exact nature of the infection he considered important. The mastoid involvement or infection might be different type on either side. In cases of sinus thrombosis, Dr. Bacon said he had seen a case in which the temperature remained high. Since the influenza otitis was apt to be of a severe type, it was wise to make an early incision in the drum membrane, even if there was but little bulging. It was a difficult matter to formulate exact rules for one's guidance for operating in cases of otitis following grippe; but, as a rule, it should be performed early if the temperature remained up. Examinations of the blood should be frequently made to see if there was a leucocytsis or not. In some cases a mastoid operation could be avoided by making incisions into the drum membrane. After mastoiditis, septic thrombosis and sigmoid disease were the most frequently met complication. Attention should be directed to thrombosis of the jugular bulb in children as well.

Dr. E. GRUENING said that since the discovery of the influenza bacillus, in 1892, they had looked for it in vain in the discharges of affected ears. If the diagnosis of influenzal otitis depended on the bacteriological proof, its existence would be problematic. In the paper read by Dr. Martha Wollstein on the bacteriology of influenza, it was stated that the influenza bacillus affected the ear secondarily. This, he understood to mean that Dr. Wollstein, in all her researches, did not find the influenza bacillus in the ear. This statement he could confirm, inasmuch as in the epidemics of influenza which they had had since 1890, the bacteriological department of Mt. Sinai Hospital never reported the finding of the influenza bacillus in the ear. What was found was in most cases the streptococcus, and only occasionally the pneumococcus. It was asserted, especially by the Halle school of otology, that the otitis of influenza did not differ in its clinical manifestations from other forms of otitis. Those who practised otology in New York before the great epidemic of influenza in 1889-90, know that the hemorrhagic forms of otitis characterized by blood containing blebs in the auditory canal and on the drum head were much more frequently observed during the prevalence of influenza than at other times. Inasmuch as the bacillus was not found in the ear, they must ascribe to the toxins of the bacillus a certain disintegrating action upon the walls of the blood-vessels. The statement made by Dr. Holt that the otologist incised the drum-head when the patient complained of pain in the ear, and the drum-head showed some redness, was erroneous. Pain in the ear and redness of the drum were no indications for paracentesis of the drum-head. The indications for the incision were given by Dr. Bacon. In order to open the drum-head, it must bulge, showing that there was fluid behind it. This fluid was either infected serum or pus, and the old principle, *ubi pus, ibi evacua*, held good, especially in that particular case. Dr. Holt's assertion that, should pain in the ear and high temperature persist after incision of the drum-head, the otologist without other indications immediately proceeded to the opening of the mastoid process, was again not borne out by actual practice. He again referred to the paper of Dr. Bacon, who gave precise indications for this operation. The otologist who would open the mastoid merely because pain in the ear and high temperatures existed, lacked both the science and the conscience of the true physician.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Special Meeting, Held January 30, 1907.

FIRST VICE-PRESIDENT, DR. H. SEYMOUR HOUGHTON, IN THE CHAIR.

Presentation of a Specimen.—Dr. EDEN V. DELPHEY presented a monstrosity.

The Medical Staff and Its Functions; A Study in Hospital Organization.—Dr. S. S. GOLDWATER presented this paper. He considered (1) the medical staff in relation to the needs of the patient; (2) the medical staff in relation to medical education; (3) the medical staff in relation to hospital economy; (4) the medical staff in relation to the rights of its members. One of the first necessities in medical organization was a system of examining candidates for admission which would guarantee a fair and intelligent treatment of all who applied. This could only be accomplished through a physician of first-rate ability and character, owing to the complex and often vital interests of applicants. Here rapid changes in office and the introduction of men of immature judgment must be avoided. Hence, in a large hospital the admitting officer must be ready to put aside the claims of private practice and to devote a large part of his time to the hospital, and the hospital should not hesitate to pay him a salary commensurate with the services demanded. In the grouping of patients and the assignment of attending physicians the hospital should avoid any undue exaltation of specialism, and yet there must be so much recognition of specialism as would encourage the development of the finest skill in diagnosis and treatment. The psychological tendencies of specialism furnished one reason for establishing such sweeping oversight of the various clinical departments as would promote their active and continuous cooperation. A single chief in command of the medical and one in command of the surgical department could do much to enhance the efficiency of the visiting staff and its subordinates. A proper organization would provide a sufficient number of attending physicians to insure prompt and efficient attention to every patient. The attending physician or surgeon should have only as many beds as he was able to keep under his eye during every day of his official duty. Once in every twenty-four hours the visiting officer must see every patient, and as much oftener as circumstances required. If this made too much of a demand on the visiting physician, let him have an adjunct or associate. Two visits daily constituted the minimum for the senior interne of the division. If in addition to the senior resident and his first assistant the house staff included at least one physician for every ward unit of twenty or thirty beds, the patient would be on a fair way to receive proper routine medical treatment. It was a wise rule which divided equally between the medical and surgical wards the work of all new men during the first year. There should be an understanding with members of the house staff that each subperiod of service would be regarded as a probationary period, and that advancement depended upon proof of fitness. The efficiency of house and visiting staff depended upon facilities for scientific investigation. In the patient's interest there must be a competent pathologist, having control over all laboratory work of the house staff. The usefulness of this department could be enhanced by admitting volunteer workers under suitable conditions. If specialists were not included in the regular visiting staff the way should be open for the utilization of their talents by naming them as a consulting staff, and they should be subject to control by the division chief similar to that of the visiting

staff. The patient's own physician should not only be tolerated in the ward, but should be welcomed both for the welfare of the patient and because he is entitled to follow his case. Upon the discharge of a patient from the hospital it was the duty of the hospital to see that he was guided into the care of the family physician or directed to the proper division of the outdoor department. An interchange of clinical records between the outdoor department and the hospital was desirable. Unity of control of indoor and outdoor departments was necessary to good hospital government. In large hospitals the supervision of the discharge of patients should be entrusted to an executive officer, preferably a medical man, who should be in touch with all charitable relief agencies in the community which were capable of dealing with any phase of physical or social needs of former patients. Hospitals which were engaged in the promotion of medical education were subject to the keenest criticism both from within and without, and owing to the rivalry among teaching institutions, were bound to favor any policy that would enhance their efficiency. So manifest were the benefits derived by the inmates of a hospital from the school atmosphere that hospitals which endeavored to promote medical education did not need to justify their policy. We were bound to recognize the training of the physician, the promotion of scientific medicine, and the dissemination of its teachings as legitimate hospital functions. The prejudice against the admission of students to the wards of the hospital was due to mistaken ideas concerning the functions and privileges of medical students in hospital wards. A belief existed that students were permitted to do much as they pleased with hospital patients, and that patients were subjected to dangerous experiments. Rational experiments in therapy and constant study of the sciences underlying the treatment of disease marked the progress of every practitioner who was successful in the better sense of that term. The presence of the student admonished the physician to exercise his best care and judgment, since to fail before a critical audience was to suffer injury to his professional reputation. The refusal of the majority of hospitals to open their doors to the students of medicine introduced unwieldly groups of learners into the few hospitals which maintained an educational policy. Once all the hospitals were brought into proper relation with the medical schools the necessity for overcrowded clinics would disappear. There was no great difference between admitting advanced students to the wards and accepting new graduates as internes. The value to medical science which lay in the carefully prepared clinical records and in the intelligent compilation of statistics must not be overlooked. This work should not be entrusted to untrained juniors or uncomprehending clerks. The association of the attending physician and surgeons with medical schools and other hospitals should be encouraged for the purpose of multiplying the sources from which knowledge might be derived. In order to extend the privileges and hospital advantages to a wide circle of the medical profession, it was advisable to limit the number of beds assigned to individual attendings and to provide a substitute for each attending. This plan was superior to one that included larger individual service with frequent rotation of duty as frequent changes interfered with continuity of study and observation which best promoted discovery. In regard to hospital economy, Dr. Goldwater said that true success of a hospital was measured by the good accomplished, and not by the assets accumulated, and the only admissible test for appointments was fitness for work. In one form only was the acceptance of money from medical workers justifiable, and that was when fees were paid by medical students in whose interests facilities for teaching were maintained. This was because of the high cost of a teaching hospital. In regard to the admission of private patients from which many hospitals derived a considerable portion of their income, he said that in charitable institutions the charity patient must not be sacrificed in the interest of income. In planning the organization of such a department the hospital would do well to extend its privileges to a circle sufficiently wide to guarantee a self-supporting department. This could be done without detriment to the charity service. While it was customary to assume that the attending staff was careless of hospital supplies, and while no doubt this was true, the underlying cause of unduly large expenditure was a disregard of economic facts in the medical organization of the hospital. There should be a chief executive officer on economic as well as other grounds. It was not reasonable to expect visiting physicians and surgeons to devote their time to a study of the details of hospital expenditure; but they should be expected to familiarize themselves with facts ascertained through systematic records showing by comparison of ward with ward the amount expended for supplies. As to the question of medical salaries: With every medical appointment there should go a suitable reward for the service exacted. For the attending physician who received opportunities for study, teaching, and prestige, there need be no question of salary; for the house staff the professional rewards were commensurate with the sacrifices made; but medical men who devoted all or a large part of their time to executive work or to laboratory duties were entitled to be paid in money. As to the rights of the medical staff, patients in private wards should pay the attending physician, but no fees should be tolerated from charity patients. There should be due recognition in annual reports of work done by the medical staff; many medical men would always contribute to the hospitals far more than can ever be repaid, and to these honor should ungrudgingly be given. Permanency of tenure should be guaranteed to those whose duties were faithfully performed. To give freest play to intellectual powers proper facilities for scientific research should be provided, and compulsory vacations should be given both for the protection of the self-forgetful worker and to give the assistant preliminary training. The physician should also have a right to participate in hospital councils.

The Medical Staff in Relation to the Needs of the Patient.—Dr. A. Alexander Smith opened the discussion on this phase of the subject. He said that the admission of patients was one of the most difficult questions in connection with hospital administration. At Bellevue it was found that the work was too much for the House Staff, and now there were four salaried physicians each on duty for six hours, thus covering the entire twenty-four hours of the day. He indorsed the plan of having a general medical and surgical chief, but thought the place a difficult one to fill. The expert surgeon too often thought his work done after he had performed the operation, while he ought to see that the patient was properly supervised. Applicants for positions on the House Staff ought not to be chosen because of their ability to pass a mental examination alone. Moral qualifications and general fitness were also essential. The attending physicians were compelled to make daily visits at Bellevue, and each attending physician had his substitute.

Dr. William P. Northrup said one secret of success in hospital service was to idealize the service. He thought twenty to thirty beds enough for one physician to visit. If the service was too large it was bad for both physician and patient. He sometimes visited his wards two, and even three times daily. These frequent visits kept nurses and staff up to the mark. The function of the hospital was to do the best that possibly could be done by the patient, and this was done when the student was admitted, as it stimulated the physician to do his work well. The visit of a body of students stimulated the whole hospital personnel as well as the physician. He was more hopeful on the subject of a general manager than Dr. Smith. He thought that the doctors had enough to do as consultants without looking out for the financial side of hospital administration. In one hospital it was the rule that physicians must first agree among themselves as to what they wanted, and then petition the lay board. This plan had worked well.

Dr. S. Lloyd disagreed with Dr. Northrup as to the mat-

ter of having doctors on the hospital board, and thought that the board should be composed entirely of physicians and surgeons. When a physician had once mastered business principles he was better qualified for hospital management than a layman. As to having a medical and surgical chief, he thought the best results could be obtained where there was such an officer, and the specialist was called in when needed. He thought there was a need for better discipline in the hospitals, and that a daily visit from the visiting physician was not as essential as thorough organization. The making of histories should not be entirely intrusted to the junior, but should be supervised by a competent physician. He thought there was too much hurry and the patients were regarded as so much machinery, and their individuality overlooked. The nervous hysterical patient needed the encouragement of the attending physician. There was a tendency to reduce the number of members of the house staffs, while we should rather seek to increase their number.

The Medical Staff in Relation to Medical Education.—Dr. SAMUEL W. LAMBERT opened the discussion on this topic. He said that this relation had always existed, and from the point of the school the desirability was self-evident and beyond discussion. The necessities of the hospitals themselves called for properly qualified graduate and undergraduate students. Teaching properly done was a help to the hospital and to the patient. In Germany both hospitals and schools were government institutions. In France their relation was recognized, and in England the school was the outgrowth of the hospital and not *vice versa*. Medical practice was of such a nature that it must be learned by experience. Most hospitals in New York City considered the practice of admitting students as a necessity to be endured rather than an advantage to be fostered. Dr. Lambert suggested that another grade be added to the regular staff known as medical clerks and surgical dressers to be filled by fourth-year students. Let the work of these helpers be such that the medical schools could accept this service in lieu of part of the fourth year's course. The mere attendance at a hospital in indiscriminate service, without any definite relation to the subject matter being studied, would be of little use; such work would have to be arranged so as to supplement the school course. While the hospital management, as a rule, did not consider that the hospital had a teaching function, the visiting staff recognized that this system was advisable.

Dr. EGBERT LEFEVRE thought Dr. Lambert's plan was not comprehensive enough. It seemed that under his plan the student was not in the hospital as a learner or observer, but simply as a clerk or dresser. The hospital should establish a regular teaching course that was definite and comprehensive. If this course could be standardized the medical college could accept it as part of the regular course. The fee paid to the hospital should be deducted from the fourth year tuition.

Dr. WILLIAM K. POLK said that as the time had come when the practitioner was expected to know more than was regarded as necessary a few years ago, likewise sanitary requirements were becoming more insistent in all parts of the country, and if the medical profession was to hold its position in the eyes of the public we must give the young practitioner the opportunity to acquire the knowledge expected of him. The profession, as a whole, was far too indifferent to medical education; that it did not seem to recognize the duty of educating those with whom it came in contact. The hospital management was apt to attribute the desire for enlargement of its field of usefulness as desired on grounds of personal exploitation, forgetting that personal exploitation was back of all success. The crying need, not only of the medical school but of the County Medical Society, was education, and this could not be had away from the bedside. It was difficult to find a satisfactory plan, as many men who were excellent visiting physicians lacked the faculty of imparting their knowledge. He thought there should be a greater use of adjuncts and shorter terms for internes as well as more internes. In regard to the undergraduate question, those who taught must show that their object was for the good of the patient rather than for the student. Bellevue was an illustration of how one of the largest clinics in the city was built up in the interests of teaching.

The Medical Staff in Relation to Hospital Economy.—Dr. A. G. GERSTER said that lack of economy in hospital administration was due to lack of stability, the constant change of staff. The House physician was there for the purpose of acquiring knowledge, and not of practising economy. The nurses were also always changing, but he thought the visiting staff ought to give the subject more attention, for if they took no interest in economy no one else would. The visiting staff should not only spend more time in the hospital, but should have regular visiting hours. Hospital expenses were increased by keeping patients too long under observation in the hospital. The dispensary should form an integral part of the hospital, and every large hospital should have a convalescent home in the country, where the patient could be well taken care of at one-half the cost of maintenance in the city.

The Medical Staff in Relation to the Rights of Its Members.—Mr. LEO ARNSTEIN said that the hospital existed for the communal good in the widest sense of that expression. If the supposed rights of the staff interfered with this communal good they were not rights. As the hospital was dependent upon the medical staff, no demand that staff could make was too great provided it did not interfere with the communal good. He did not believe in a board composed entirely of medical men; usually it was safe to leave the good of the community in the hands of a third party, and this should be the lay board.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON DERMATOLOGY.

Stated Meeting, Held January 8, 1907.

DR. A. R. ROBINSON, IN THE CHAIR.

Neurotic Eczema with General Alopecia.—Dr. BULKLEY presented this patient, a girl fourteen years of age. Her father was said to have had eczema in childhood, and her mother was nervous. The patient had measles and varicella in childhood, but never diphtheria. For about two years, from two to four years of age, she had a generalized eczematous eruption. Her teeth and finger nails had always been bad, and she had noticed no change in them as a result of the present disease. She had always been nervous, but had had no serious illness. Her menses were regular and painless. She had never noticed either axillary or pubic hair. The present eruption began last August, coming first on the abdomen, then on the arms and neck, and in October or November spreading all over the body. There was no history of nervous shock, but at the time of the onset she was overtired from loss of sleep. The hair began to fall in October, beginning on the vertex, and reached the present condition in about six weeks. When presented before the Section, the scalp showed several large, very irregular, but fairly sharply defined areas over which the skin was smooth, slightly atrophic, and bald, while between these areas the skin was thicker, and showed a good many stubs and a few long hairs. Scattered over the scalp were the stains and dry crusts left by the antecedent eruption. The eyebrows were gone, the eyelashes were thin, and there was no hair in the axillæ, or over the pubes. All the finger nails, except that of the middle finger of the right hand, were pitted, the pits being arranged roughly in parallel horizontal lines. The distal half of each incisor tooth was badly eroded. Scattered over the whole surface of the body were irregular, poorly defined areas of eruption, consisting of itching red pupules and papule vesicles. Where the eruption was more intense the elements ran together to form weeping surfaces, as in the bends of the elbows and over the manubrium sterni.

Dr. Pollitzer said the case was not one of typical alopecia areata. He thought the condition was due to some form of intoxication.

Dr. Holder agreed with Dr. Pollitzer that a general toxic disturbance would account for the universal change in the skin. The skin on the back seemed to have the follicles plugged by horny tissues, giving the skin an appearance of unusual roughness.

Dr. Leviseur, from the anemic appearance of the patient, believed this case to be one of leukemia, and the skin affection, as well as the loss of hair, to be one of those cutaneous complications not infrequently appearing in connection with leukemia and pseudoleukemia. He asked if a blood examination had been made.

The Chairman believed also that some profound disturbance or intoxication was present to account for some of the conditions. As regarded the alopecia, the facts that there were no circular bald patches, that bald patches did not form by falling out of hair at the periphery, and, finally, that very many of the hairs were broken off, would, in his opinion, exclude the diagnosis of alopecia areata. He regarded the alopecia as connected with organisms in the scalp, and probably the same ones as caused the seborrheal eczema.

Dr. Bulkley, closing the discussion, reminded those present that the structure of the hair, nails, and epidermis were all much the same, and that they had all shared in the same degenerative process. He also called attention to the teeth, which were all misformed, indicating that a depraved vitality had been in operation for some time. He did not look upon the girl's condition as due to toxemia, or autointoxication, like that found in urticaria, and did not believe that a toxemic condition could produce such profound alterations. The entire condition could come from some nervous shock or strain, affecting the nutrition of the tissue, a degenerative neurosis. She had an early history of eczema, at four to five years of age, and the skin was likely to take on eczema again, so that he would regard the present condition of the skin as a neurotic eczema, with possibly alopecia areata of the eyebrows, but the loss of the hair on the scalp could hardly be regarded as the latter. The patient had just only entered the New York Skin and Cancer Hospital, and had had very little treatment as yet. While the history presented stated that the disease dated back only a few months, he felt sure from the teeth, nails, and hair that some disturbance of nutrition, probably of neurotic nature, had been going on for a long time.

Lupus Vulgaris.—Dr. Bulkley presented this patient, a woman, thirty-four years of age, from Dr. Fox's service at the New York Skin and Cancer Hospital. She had had the disease since three years of age, and had been subjected to much treatment. Some of the diseased tissue was removed and skin grafting performed eight years ago. For two years she had been in the New York Skin and Cancer Hospital, under the care of Dr. Fox, who had treated many of the lesions with the dental burr, and more recently had treated the lesions on the mucous surface of the upper lip with electrolysis. When shown before the Section, the condition was largely the result of the past disease and of treatment, there being few lesions which could be recognized as lupus vulgaris. The nose was greatly disfigured, a good part of the right ala being gone. The affected area covered also most of the left side of the face, which was irregularly scarred, with great ectropion of the left eye, for which a plastic operation had been performed, with partial success.

Dermatitis Papillaris Capillitii.—Dr. Leviseur presented a man thirty-five years old, who five years ago had what was supposed to be a boil on the vertex of his scalp. It was an elevation the shape of a cherry, not painful, and discharged a sticky material. As local applications did not benefit it, the tumor was opened extensively, the operation leaving a keloidal scar three inches long and a quarter of an inch in width. From time to time, in the vicinity of this bald spot, there appeared rather suddenly pea-sized nodules, which grew, opened, and discharged a small amount of pus. Some of them disappeared occasionally; others remained and became covered with wart-like excrescences rather hard, and perforated by a number of hairs bunched together. When the patient first came to Dr. Leviseur on November 25 he had five distinct lesions aside from the keloidal scar, two immediately at its border, the others scattered about, but not far removed. It was quite easy to puncture the lesions, some of which had no opening, and the probe went in very deep, particularly on the tumor covered with papillomatous formations. The patient's hair was very coarse. He was a letter carrier and wore a tight-fitting cap. The sebaceous follicles connected with the hairs all over the scalp presented a comedo-like appearance. The diagnosis dermatitis papillaris capillitii was made, although the localization was rather exceptional. The lesions, particularly those covered with warty growths, were cauterized with nitric acid and disappeared, but a few follicular nodules formed again, always in the vicinity of the old lesions. The hair had grown somewhat thin in the whole region. Microscopically there were no changes in the hair. Thorough destruction of the individual spots seemed to be the only therapeutic measure which benefited the patient.

Dr. Lapowski said that he did not consider the case to be one of Kaposi's dermatitis papillaris capillitii, but thought it to be an infectious folliculitis. In Kaposi's disease the lesions were harder and more infiltrated. In cases which had come under his observation, he had not seen such lesions as appeared in this case. He would like to see the appearance of these lesions after being treated for a month with mild antiseptics only.

Dr. Bulkley said that, while the condition present might in a measure suggest dermatitis papillaris capillitii, he did not feel that it could quite properly be classed with those cases thus described—although undoubtedly there was a dermatitis. He regarded the trouble simply as one due to ordinary pus infection, modified by treatment. The sebaceous glands of the scalp being very large and deep seated, there was always deep inflammation when they were thoroughly infected, and this he had often seen to be a very chronic nature: the results of inflammatory action could readily give rise to the apparently papillomatous condition.

Dr. Leviseur, closing the discussion, said that the papillomatous feature of the lesions was missing on account of the removal of the warty excrescences by strong caustics, and apologized for showing the case in this condition. The duration of the disease, five years, its localization near the keloidal scar, its resistance to ordinary treatment alone, seemed to him to militate against a diagnosis of simple folliculitis or sycosiform staphylococcus infection.

Raynaud's Disease Probably of Syphilitic Origin.—Dr. Lapowski presented a man thirty years of age, a Pole by birth. He was married and had two children, three years and one year old respectively, and his wife had had no miscarriage. Both family and personal history were negative, there being no history nor visible symptom of any form of intoxication in the patient, who was a man of temperate habits, a clothing-cutter by occupation. His present trouble had begun in the winter three years before, with pain in the tip of the middle finger of the right hand. The pains were remittent, and appeared without any premonitory symptoms, accompanied by a very cold feeling in the finger tips. The finger nail was removed by a physician, and gradually a gangrenous condition developed in the third phalanx, necessitating its amputation. Dr. Lapowski saw him for the first time at the Good Samaritan Dispensary in the winter of 1905, with pain and slight suppuration of the tip of the middle finger of the left hand. The patient was then given potassium iodide, but he disappeared, returning after several months of great improvement; the tips of the fingers were thinner, only slightly cyanotic, neither ulcerated nor painful. This improvement was the result of anti-

syphilitic treatment (inunctions, injections, and potassium iodide) which he had received at the Mount Sinai Hospital. Two months later the tip of the right ring finger became cyanotic and swollen, but improved under antisyphilitic treatment. Two months ago he began to have pains in the left second toe, accompanied by a cold feeling. Since 1905 he had been sexually impotent. When shown before the Section, he was pale and tired looking. The middle finger of the right hand lacked the terminal phalanx, which had been amputated three years before. The stump was cold to the touch, swollen, slightly cyanotic, and the skin was tight, so that he could not bend the phalangeal joint. The metacarpo phalangeal joint was normal. On the right index finger the nail bed was white from the lunula to the anterior third; the surface of the nail was smooth. The terminal phalanx of the fourth finger of the right hand was cold and swollen, the peronychium and the part around the lunula were red. The entire nail was raised from its bed, the entire matrix hypertrophied, and the space between the body of the nail and the matrix filled with dry, whitish, hard particles. The right little finger was slightly cyanotic. The left index finger had a thin conical terminal phalanx, and the patient could not bend the joint between it and the second phalanx; there was only the remnant of a nail. The first phalanx of the big toe of the left foot was swollen, cyanotic, painless to the touch, and cold. On the lower surface of the toe there was a pea-sized ulcer, with grayish floor, and sharply cut edges; neither the surrounding tissue nor the base was infiltrated. The sore was painful to the touch. The second toe of the left foot had a round infiltration, occupying the region over the joint between first and second phalanges. In the center there was a pea-sized ulcer with a necrotic center and slightly raised edges. The whole toe was cold to the touch, cyanotic, and painful. The right little toe was cyanotic. The nose and ears were normal. The pulse was small and hardly perceptible in either the radial or the perineal arteries. There was no albumin in the urine. The heart and lungs were normal.

Dr. Holder said that the case was undoubtedly one of Raynaud's disease. The improvement under antisyphilitic treatment suggested a syphilitic origin in spite of the failure of Dr. Lapowski to obtain a history of syphilis in his patient. The coldness and cyanosis of the fingers indicated some interference with the arterial circulation, and were the most important symptoms in making the diagnosis of Raynaud's disease.

Dr. Bulkley remarked that we did not yet know the entire clinical history of syphilis. He regarded it as an important fact that the man, although he denied syphilitic disease, was born in Russia. There were areas in Russia where there were great numbers of syphilitics; indeed in some districts almost the entire population had been at some time infected, many being infected in infancy by household utensils, nursing, etc. These cases were frequently untreated, and showed the results of syphilis in later life. He recalled the fact that Dr. Fox showed a case at a meeting of the New York Dermatological Society, some time ago, in which a similar condition was going on in the toes. One of the toes had been amputated, and gummatous tissue was forming around. The case was originally shown as a possible case of Raynaud's disease, with cold toes, etc. This man was entirely cured with antisyphilitic treatment, the speaker himself having watched the case with interest in the New York Skin and Cancer Hospital. Syphilitic arteritis manifested various symptoms, some of which easily resembled Raynaud's disease, for this in reality was often only a name to cover a certain group of symptoms. He thought that some of the lesions on the toes suggested diffuse form of gummatous syphilitic infiltration; he would put the patient at once on a strong mixed treatment, and believed that he would recover completely.

The Chairman agreed with the diagnosis of Raynaud's disease or local asphyxia. He was not so positive that the gangrenous lesions were to be regarded as simply gummatous, that sections would show the anatomical character of ordinary gumma. As regarded the treatment of these cases, he would state that the first case under his observation had a syphilitic history and was treated by iodides without any benefit, but perhaps the dose given was too small. The patient was a physician, and the first post mortem made in this disease was upon this patient.

Dr. Lapowski, closing the discussion, said that when the patient came to the Good Samaritan Dispensary in 1906 with a gangrenous condition of the finger tips, there was not the slightest clinical resemblance to syphilis. Nevertheless, a great improvement followed the use of antisyphilitic treatment. This showed that in cases of so-called Raynaud's disease, even if there were no specific symptoms, it was advisable to use mercury. He promised to give this patient inunctions and calomel injections, and to present him at the next meeting.

Dr. Lapowski reported that the man presented by him October 30 as a patient with a tuberculide, had received four calomel injections. There was great improvement after each injection, but a new eruption appeared on the arms and thighs, starting with the sudden appearance of a tubercle under the skin; the skin itched and the epidermis was scratched off, leaving a slightly depressed center, which gradually underwent necrosis. He had never seen such an eruption in syphilis. He would give him no more injections, and hoped to present him at the next meeting.

Dr. Lapowski also reported that he had found the *Spirochæta pallida* in each one of the three chancres on the man presented at the December meeting.

The Williamsburg Medical Society.

At the first regular meeting of this society, held January 9, 1907, the President, Dr. Leon Loeria, in his inaugural address, explained that the aims of this new society were not merely to provide a lecture room for favored speakers, but mainly to establish a forum in which all its members could voice their opinions. Besides inviting the aid of outside medical forces, and the views of specialists in medicine, it was to reserve the larger part of its program for its own members, who, although affiliated with other organizations, rarely took part in their discussions. It was urged that those whose opportunities for hospital and research work were limited, were nevertheless fitted to speak with the authority that bedside observation conferred, for this observation was the source of most medical knowledge. The recital of a case was usually the means of bringing forth new light and discovering new ideas. Dr. Jacob Fuhs presented and gave the history of a case of "Raynaud's disease." The patient, a girl nineteen years old, at the age of [illegible] had an arrest of growth. Four years later she was treated for rheumatic pains in the hands and feet. A year later she complained of her stomach, had a [illegible] and passed per rectum as much as a quart of blood. A possibility of typhoid had been suggested. Four years later, complaining of epigastric pain, she had come under the care of the speaker, and improved under a diet and with alkalies. Under thyroid medication she had grown four inches. For past two winters she had noticed that when placed in water her fingers and toes would turn white and lose all feeling. This had not occurred during the summer. During the past winter some of the fingers and toes [illegible] were purple, and subsequently gangrenous spots appeared on the hands and feet. Apart from these [illegible] manifestations of local syncope, asphyxia, and gangrene, examination revealed nothing except the [illegible], height and a slight enlargement of the [illegible] and duplication of the second pulmonic sound. There was [illegible] anæmia. Dr. Fuhs also read a paper on "Ulcerations of the Stomach," based on three cases that he had recently seen.

The lesion revealed a chronic catarrhal gastritis with chronic interstitial infiltration with, in one case, atrophy of the glands. Although epigastric pain was not, as a rule, severe, epigastric tenderness was present in all cases, but this was not located at Boas' point. Usually there was moderate emaciation. The diagnosis depended on finding pieces of gastric mucosa in the stomach washes, the epigastric tenderness, and the persistence of the disease for years. It was necessary to distinguish this disease from cancer and ulcer. The treatment included diet, rest, and the use of bismuth and silver nitrate. Dr. SAMUEL M. BRICKNER of New York read a paper entitled "The Rational Treatment of Fever in the Puerperium." He deprecated the unnecessary labeling of most diverse conditions as "puerperal sepsis," and emphasized the importance of making a pathological diagnosis. Apart from other conditions, such as lobar pneumonia, pulmonary infarct, mastitis, thrombophlebitis, typhoid fever, malaria, or any other acute infectious, fever in the puerperium was due to any one of many lesions in the genital tract, which were classified under the heading puerperal sepsis as distinguished from extragenital sepsis. Of the former, one had to consider extrapelvic and intrapelvic lesions. The extrapelvic lesions included vulvar and vaginal forms of sepsis and conditions in the abdominal wall. The physician frequently succeeded in carrying, by means of the intrauterine douche, an infection from the vulva, where it was harmless, to the uterus, where it would become fatal. For the vaginal and vulvar lesions mild antiseptic douches were all that was necessary, with a gauze drain and a wet dressing to the vulva. Of the intrapelvic lesions, the speaker confined his remarks to only three conditions. One of these was uterine sepsis resulting from premature rupture of the membranes, with delay in the onset of labor beyond eighteen to twenty-four hours, and the introduction of septic material from without. To avoid this he advocated the induction of labor. The next form was that due to retained secundines. It was a false theory that advised entrance into the uterus for a small piece of placenta or a shred of membrane. These usually came away by themselves. The third condition discussed was that of retroversion or retroflexion of the uterus, causing retention of lochia.

Status Lymphaticus; Its Significance in Sudden Death Following Serum Injections and in the Treatment of Diphtheria.—A. P. Ohlmacher defines status lymphaticus as a so-called constitutional disorder whose chief anatomical characteristics are a persistent or hyperplastic thymus and general lymphadenoid hyperplasia, frequently associated with hypoplasia of the arteries and heart, and the osseous or other changes of rickets. Many competent authorities ascribe to the lymphatic state a distinct relationship with certain neuroses, including the so-called "thymic" sudden death. As to the treatment of this condition, aside from measures indicated for rickets when this disorder exists, there are no therapeutic resources. The writer believes that it is entirely justifiable to conclude that most, if not all, of the fatal accidents of serum therapy are examples of lymphatic sudden death. The status lymphaticus predisposes to an enfeebled resistance against infections, particularly against diphtheria. Information concerning status lymphaticus and its neuroses, especially those in the category of sudden death, should be more widely disseminated. The writer concludes that no questionable case in which death has followed a serum injection should be permitted to close without a thoroughgoing autopsy, having in view the possibility of disclosing the anomalies of status lymphaticus. And both to protect the reputation of the specific remedy for diphtheria—the antidiphtheritic serum—and that of the physician, the significance of status lymphaticus as modifying the prognosis, course, and treatment of diphtheria should be kept clearly in view.—*Detroit Medical Journal.*

Surgical Suggestions.

Rectal Feeding.—The conditions that must be present in order for attempts at rectal feeding to be successful are summed up by Becker as follows: (1) The rectum must be in a fairly normal condition. Inflammation of any kind, especially eczema, internal piles, or pressure by the fundus or cervix uteri upon the rectum, must be absent. If such conditions do exist, they must be ameliorated if possible. (2) The rectum and descending colon must be free from contents. (3) The composition of the food introduced must correspond to physiological exigencies of the rectum and colon. (4) The food must contain as much nutrition as possible, condensed to as little volume as possible. The volume should never exceed 250 c.c. (5) The temperature of the food is of great importance. It should range between 42 and 45 degrees C. (6) The rectum and the colon should be quieted an hour before and a few minutes after the meal with an opium and belladonna suppository—not morphine, which has a tendency to produce vomiting.—*Wisconsin Medical Journal.*

Iodine Catgut.—The value of the iodine method of sterilizing catgut is being universally recognized, and Burmeister states that he has obtained the best results by using a solution containing 1 g. of iodine in 15 c.c. of chloroform. The catgut is immersed in this solution, and is ready for use at the end of a week. He considers that catgut prepared in this way is superior to that made by using aqueous or alcoholic solutions of iodine, in tensile strength, absence of irritating qualities, and in the fact that it does not swell in the tissues.—*Zentralblatt für Chirurgie.*

Bichloride Gauze.—According to Powell, the following is a convenient method of preparing this surgical dressing: Take ordinary cheese-cloth and boil in water made alkaline by the addition of common washing soda; wring the cloth out in hot water; boil again in plain water; then run through a bichloride solution 1:200 and pack away moist in sterile jars. This gauze, immediately before using, should be wrung out in a solution of bichloride, 1:1000.—*The Clinical Review.*

Tattoo Marks.—Variot of Paris proceeds as follows: Apply under antiseptic precautions a concentrated solution of tannin to the skin and work it in as in tattoo operation. Then rub skin with pencil (or solution) of silver nitrate until the tattoo marks stand out as black points on the silver tannate. Excessive fluid should be removed; the surface turns black and moderate inflammation follows. In fourteen days the eschar drops off, leaving a red superficial cicatrix which fades in seven or eight weeks." This plan is safe and sure—but painful and tedious. Ordinary slight tattoo marks (powder marks, etc.) may often be removed by pricking in peroxide of hydrogen. Another plan is to tattoo well over mark with needles dipped in a solution of chloride of zinc thirty parts, distilled water forty parts. Eschar drops in two weeks. Then dress area with simple cerate. The fact that the insoluble substances which are used in tattooing become encapsulated explains the difficulty experienced in their removal. Under the microscope excised portions of tattooed tissue show large particles of pigment situated part in the corium but more generally in the subcutaneous connective tissue itself. In the method by electrolysis the needle is attached to the negative pole of a battery with a current of from two to ten milliamperes and inserted at various points about the periphery of stained area till reaction is marked enough to insure destruction of involved tissue. The dry superficial eschar falls in a few days and the process may be again employed over the adjacent skin.—*The American Journal of Clinical Medicine.*

Irritation of the Epiglottis for Resuscitating the Apparently Asphyxiated.—Tickling the epiglottis with the finger has been found by Friedenthal to be a highly effective method of resuscitating those who are in a state of asphyxia from drowning, anesthesia, etc. He describes the procedure in this way. The method, he says, consists in introducing the hand into the mouth of the patient until you feel the epiglottis and then moving the index finger to and fro over the epiglottis. Thus a very powerful effect is exercised directly upon the nerves to be considered in this connection, viz., the glossopharyngeal supplying the anterior surface of the epiglottis and the inner branch of the superior laryngeal nerve supplying the posterior surface of the epiglottis, the base of the tongue, etc. The epiglottis is that organ of the human body which is particularly capable of inducing reflex action on the least irritation, and we all know how much difficulty we often have to avoid this irritability in laryngeal work. And this is just what we need in asphyxial conditions whatever be their cause.—*St. Louis Medical Review.*

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

VERMONT STATE BOARD OF MEDICAL REGISTRATION.

January, 1907.

CHEMISTRY.

1. (*a*) Discuss the chemical characteristics of a good drinking water. (*b*) State the most important fact about hydrogen.
2. Name two gases that have not been liquified.
3. (*a*) How is H_2O_2 made? State strength. (*b*) Name four alkali metals and give symbol of each.
4. (*a*) Mention the principal proteids of nerve tissue. (*b*) What is saccharin?
5. (*a*) Define urobilin, urochrome, uroerythrin. (*b*) What leaves the body mainly through urea? (*c*) Give test for urea and state number of grains normally excreted in twenty-four hours.

MATERIA MEDICA.

1. (*a*) State dose and strength of dilute hydrocyanic acid. (*b*) What preparations used in medicine contain it?
2. Give the composition, uses, and dose of the following preparations: (*a*) Spirits of Mindererus, (*b*) compound syrup of squills, (*c*) Pearson's solution, (*d*) Griffith's mixture, (*e*) brown mixture.
3. Name the alkaloids, preparations, and doses of ipecac.
4. (*a*) Give the source, dose, and action, of the following alkaloids: sparteine, berberine, atropine, narceine. (*b*) Give the strength of the following: tincture of capsicum, tincture of rhubarb, tincture of colchicum seeds, tincture of digitalis, tincture of aconite, tincture of hyoscyanus, tincture of veratrum viride, tincture of belladonna.
5. Discuss the composition and physiological action of ergot.

THERAPY.

1. Briefly explain:—natural therapeutics, empirical therapeutics, rational therapeutics.
2. Write a formula for each of the following: acne rosacea, hysteria, angina pectoris, bronchiectasis, chronic nasal catarrh, enuresis, diabetes insipidus, hepatic cirrhosis, hiccough, influenza.
3. How would you treat and manage a case (*a*) of infantile convulsions? (*b*) of renal and vesical calculi?
4. Mention the indications for the following drugs: potassium chlorate, salicylic acid, phosphorus, chloral, cantharides, carbonate of ammonia, potassium bromide, elaterium, guaiacol carbonate, stramonium.
5. Give your drug and dietetic treatment of typhoid fever.

ANATOMY.

1. Describe the bones of the foot, giving their divisions and articulations.
2. Describe the occipitoatloid articulation.
3. Name the superficial muscles of the neck and scalp, and give the origin, insertion, and nerve supply of any one of them.
4. Describe the portal system of veins.
5. Give the origin, course, and termination of the thoracic duct.
6. State the origin, course, and distribution of the sixth pair of cranial nerves.
7. Describe the special organs of taste, and give their nerve supply.
8. Name the coverings of femoral hernia from without inward.
9. Describe the prostate gland and give its relations.
10. Give the normal position, size, form, ligaments, blood, and nerve supply of the uterus

PHYSIOLOGY.

1. Give the classification of nerves.
2. Of what does the cerebrospinal axis consist?
3. Name the coverings of the brain, and describe them.
4. Describe and give location of the corpora quadrigemina, also give function.
5. Describe healthy urine, and give constituents.
6. What are enzymes? State the special functions of each enzyme concerned in digestion.
7. Describe the proteid digestion, and name the ferments concerned therein.
8. Into how many classes are food stuffs divided? Name them.
9. What is meant by the automatic action of the spinal cord? Give three examples.
10. Name some of the kinds of cells found in man. What is epithelium? What are its varieties?

HYGIENE.

1. What is meant by personal, domestic, and public hygiene?
2. What is the distinction between sewer air and sewer gas? What gives sewer gas its peculiar odor?
3. Give the hygiene of the secretory organs.
4. How do disease germs produce their characteristic effect on the system?
5. What constitutes a thorough inspection of milk as to food value and purity?

BACTERIOLOGY.

1. Classify bacteria, and state the difference between a saprophyte and a parasite.
2. State the difference between a toxin and a ptomain. Give five sources of ptomain poisoning.
3. Describe the gonococcus, and give method of staining the same.
4. State microscopical appearance, and staining peculiarities of the tubercle bacillus.
5. What evidences of contamination of drinking water may be obtained by bacteriological analysis? Compare the value of chemical analysis with that of bacteriological analysis.

PATHOLOGY.

1. Give the pathological difference between moist and dry gangrene.
2. Give the pathological anatomy of lobar pneumonia.
3. Give the pathology of carcinoma.
4. Give the pathology of typhoid fever.
5. Give the pathology of chronic arteriosclerosis.

PRACTICE.

1. Give the treatment, including preventive treatment, of typhoid fever, also that for the more common complications of this disease.
2. Give the etiology of, and describe the different types of influenza.
3. Give the differential diagnosis (*a*) between rubeola and rubella, (*b*) between rubeola and scarlatina.
4. Give differential diagnosis between variola and varicella.
5. Give the period of incubation of the diseases mentioned in questions 3 and 4, also the proper period for quarantine in each.
6. (*a*) Mention the different types of pneumonia; (*b*) give its treatment.
7. Differentiate betwixt cardiac hypertrophy, cardiac dilatation, and pericarditis with effusion.
8. Write a short article on hemophilia.
9. How would you manage a case of chronic interstitial nephritis?
10. Give the symptomatology of tabes dorsalis.

SURGERY.

1. What are toxins, antitoxins, and phagocytes?
2. Describe four methods of reducing dislocation of the shoulder.
3. How would you treat a fracture of the elbow joint?
4. What is septicemia and pyemia? Give causes.
5. Differentiate between acute ovaritis of the right side and appendicitis.
6. Describe the mastoid operation for suppuration.
7. Name and describe four forms of talipes.
8. Describe fistula in ano, and give treatment.
9. Give symptoms of acute cystitis, and write a prescription for same.
10. Describe in detail Bassini's operation for inguinal hernia.

OBSTETRICS.

1. Enumerate signs of pregnancy and indicate relative importance.
2. Describe the management of a case of R. O. P. presentation.
3. Give symptoms, diagnosis, and treatment of placenta previa.
4. Give causes and treatment of mastitis.
5. What, how often, and how much would you feed a baby one week old?
6. Name at least six of the most common conditions calling for the use of forceps.
7. Give management of a case of miscarriage.
8. Give prophylactic treatment of postpartum hemorrhage.
9. Give treatment of puerperal sepsis
10. Give diagnosis and treatment of extrauterine pregnancy after rupture.

GYNECOLOGY.

1. Describe the uterus.
2. Give causes and treatment of ovaritis, acute and chronic.

3. Give symptoms and treatment of retroversion of uterus.
4. Give contraindications for use of uterine sound.
5. Give symptoms and treatment of acute vaginitis.

LEGAL MEDICINE.

1. Give a definition of a medicine, also of a poison.
2. Give examples of mania, monomania, dementia, and idiocy.
3. What is the difference between civil and criminal malpractice?
4. Give your reasons that a child had been born alive.
5. Describe a bullet wound, entrance and exit.

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

VERMONT STATE BOARD OF MEDICAL REGISTRATION.

January, 1907.

CHEMISTRY.

1. (*a*) It should be colorless, odorless, cool, limpid, soft; it should have an agreeable taste, neither sweet nor salty nor flat; it should dissolve soap readily without formation of a curdy precipitate; it should contain not more than twenty-five to thirty grains of harmless solids per gallon, and should not be contaminated with sewage, lead, or other poisons, or pathogenic bacteria.

(*b*) There is no most important fact about hydrogen; the following are all of them facts, the relative importance of which must be decided by the examiner for himself: Hydrogen is a necessary element in the composition of all acids, also of water; the weight of its atom is the unit by which all atomic weights and molecular weights are measured; it is the lightest known substance.

3. (*a*) H_2O_2 is made by adding barium dioxide to a solution of dilute hydrofluoric acid. The strength is a ten to twelve volume solution.

(*b*) Lithium, Li.; Sodium, Na.; Potassium, K.; Rubidium, Rb.

4. (*a*) Albumin, globulin, nucleoproteid, and neurokeratin.

(*b*) Saccharin is benzoyl sulfonic imid, or anhydro-ortho-sulphamine-benzoic acid

5. (*a*) *Urobilin* is a brownish pigment found in the urine, the feces, and sometimes in the blood.

Urochrome is a yellow pigment of the urine.

Uroerythrin is a reddish pigment sometimes found in the urine.

(*b*) Nitrogen.

(*c*) A comparatively easy test is that of Fowler, based upon the loss of the specific gravity of the urine after the decomposition of the urea by hypochlorite. "To apply this method the specific gravity of the urine is carefully determined, as well as that of the liquor sodæ chlorinatæ (Squibb's). One volume of the urine is then mixed with exactly seven volumes of the liquor sodæ chlorinatæ, and, after the first violence of the reaction has subsided, the mixture is shaken from time to time during an hour, when the decomposition is complete; the specific gravity of the mixture is then determined. As the reaction begins instantaneously when the urine and reagent are mixed, the specific gravity of the mixture must be calculated by adding together once the specific gravity of the urine and seven times the specific gravity of the liquor sodæ chlorinatæ, and dividing the sum by eight. From the quotient so obtained the specific gravity of the mixture after decomposition is subtracted; every degree of loss in specific gravity indicates 0.7501 gram of urea in 100 cc. of urine. The specific gravity determinations must all be made at the same temperature, and that of the mixture only when the effervescence of gas has ceased entirely." (Witthaus' *Manual of Chemistry*.)

MATERIA MEDICA.

1. (*a*) Doses: [illegible] of minims; *strength* is two [illegible]

(*b*) [illegible] Salicylic [illegible] benzoic

[illegible] of Hydrastis Canadensis

2. (*a*) *Solutio* of Mindererus [illegible] solution of [illegible] per cent.

[illegible] of the [illegible] carbonic acids

[illegible] four drams.

(*b*) *Compound syrup* of *squill's* contains fluid extract [illegible] of senega, tartar emetic, sugar, chloric phos[illegible] water. Dose, half a dram

(*c*) Pearson's *Solution* solution of sodium arsenate, [illegible] of the alcohol water. Dose, three minims.

(*d*) *Griffith's mixture* is compound iron mixture, and contains ferrous sulphate, potassium carbonate, myrrh, sugar, spirit of lavender, and rose water. Dose, four drams.

(*e*) *Brown mixture*, is compound mixture of glycyrrhiza, and contains extract of glycyrrhiza, syrup, acacia, wine of antimony, spirit of nitrous ether, camphorated tincture of opium, and water. Dose, two drams.

3. *Alkaloids:* Emetine, cephaeline, and a third, unnamed alkaloid.

Preparations and Doses: Fluid extract, ♏xv; powder of ipecac and opium, gr. viiss; syrup of ipecac, ♏xv, as an expectorant, ℥iv as an emetic; wine of ipecac, ♏xv; tincture of ipecac and opium, ♏viij.

4. (*a*) *Sparteine*, from scoparius, sparteine sulphate, gr. 1/5; *berberine*, from hydrastis, calumba, berberis, and other plants, berberine sulphate, gr. ss. to gr. jss; *atropine*, from atropa belladonna, gr. 1/100; *narceine*, from opium.

(*b*) The tinctures of capsicum, colchicum seeds, digitalis, aconite, hyoscyamus, veratrum viride, and belladonna are ten per cent. strength; tincture of rhubarb is twenty per cent. strength.

5. The composition of ergot is indefinite; the chief constituents are: Ergotine, ergotinine, ecboline, sphacelic acid, ergotinic acid, cornutine, tannic acid, and other substances. Most of these ingredients contract the blood-vessels; the cornutine, in addition, is credited with the chief part in contracting the uterus.

THERAPY.

1. *Natural therapeutics* comprises the processes which may be included under the general heading of the healing or recuperative powers of the organism itself, independently of any outside aid. Rest and sleep are examples.

Empirical therapeutics is a term applied to such remedies as are used simply because they have been found beneficial in certain cases.

Rational therapeutics means the use of remedies based on a combined knowledge of their physiological action and of the pathological condition present in the patient.

2. For *acne rosacea:*—℞ Zinci sulphatis
Potassii iodidi āā ℥ss
Aquæ rosæ, q. s. ad ℥iv. Misce
Sig: Use as a lotion.

For *hysteria:*—℞ Tincturæ asafœtidæ
Tincturæ valerianæ ammoniatæ āā ℥j
Aquæ camphoræ, q. s. ad ℥iij. Misce
Sig: One tablespoonful every hour.

For *angina pectoris:*—℞ Pearls of nitrate of amyl, ♏iij. No. x.
Sig: Crush one and inhale when required.

For *bronchiectasis:*—℞ Potassii iodidi ℥j
Glycerin ℥iij
Syrupi senegæ ℥j
Aquæ destillatæ q. s. ad ℥iij. Misce.
Sig: A dessertspoonful one hour after meals.

For *chronic nasal catarrh:*—℞ Sodii boratis
Sodii bicarbonatis āā ℥ss
Phenol gr. xv
Glycerini ℥ss
Aquæ destillatæ O. j. Misce.
Sig: Use as a spray.

For *enuresis:*—℞ Potassii citratis ℥ss
Spiritus etheris nitrosi ℥vj
Aquæ destillatæ q. s. ad ℥ij. Misce
Sig: A dessertspoonful every four hours.

For *diabetes insipidus:*—℞ Fluidextracti ergotæ ℥iss
Aquæ destillatæ q. s. ad ℥iv. Misce
Sig: One teaspoonful, three times a day.

For *hepatic cirrhosis:*—℞ Potassii iodidi ℥ijss
Aquæ destillatæ ℥ij. Misce
Sig: One teaspoonful in a tumbler of water one hour before meals

For *hiccough:*—℞ Spiritus etheris compositi ℥j
Sig: One teaspoonful in a glass of ice-water.

For *influenza*—℞ Quininæ hydrobromatis
Sodii benzoatis
Caffeinæ āā gr. xx. Misce, et fiat massa in pilulas No. xx, dividenda
Sig: Take one three times a day.

ANATOMY.

8. Skin, superficial fascia, cribriform fascia, crural sheath, septum crurale, subserous areolar tissue, and peritoneum

PHYSIOLOGY.

1. Nerves are classified as—I. Efferent nerves, or centrifugal nerves, which may be motor, accelerator, inhibitory, secretory, or trophic nerves. II. Afferent nerves, or centripetal nerves, which include nerves of general sensation, special sense and of pain. III. Intercentral nerve fibers, which connect different parts of the nervous system.

4. The corpora quadrigemina are four small rounded eminences situated over the aqueduct of Sylvius. They are arranged two on each side behind the pineal body, and are separated from each other by a crucial depression. They are white on the surface, but contain gray matter in the interior. As to their *function*, they contain centers for the contraction of the pupils and for the coördination of the movements of the eyeballs.

6. Enzymes are unorganized ferments which are the result of the activity of special cells of the animal body.

	ENZYME.	FUNCTION
Saliva	Ptyalin.	Changes starches into dextrin and sugar.
Gastric juice	Pepsin.	Changes proteids into proteoses and peptones in an acid medium.
	A curdling ferment.	Curdles the casein of milk.
Pancreatic juice	Trypsin	Changes proteids into proteoses and peptones, and afterwards decomposes them into leucin and tyrosin; in an alkaline medium.
	Amylopsin	Converts starches into maltose.
	Steapsin.	Emulsifies and saponifies fats.
	A curdling ferment.	Curdles the casein of milk.

8. Food stuffs are divided as follows:—

I. Inorganic: Water. Salts.

II. Organic: Non-nitrogenous: Carbohydrates. Fats. Nitrogenous—Proteids.

9. By automatic action of the spinal cord is meant that property of the nerve cells of the cord by virtue of which they become active as the result of changes within the cord, and without any external stimulus. Some of the centers in the cord may act automatically, but as a rule they act as reflexes in response to external stimuli. Examples are parturition, defecation, and micturition.

HYGIENE.

2. *Sewer air* is atmospheric air with its oxygen diminished and its carbon dioxide increased from 0.04 per cent. to 0.4 per cent., and contaminated with more or less marsh gas, sulphuretted hydrogen, ammonium sulphide, etc.

Sewer gas "is but a mixture of a number of gases, such as carbonic acid, carburetted hydrogen, ammonium and hydrogen sulphide, nitrogen, etc., together with a considerable amount of fetid organic matters, the volatile or semi-volatile products of animal and vegetable decomposition, varying according to the condition of the sewer, the kind of matter received therein, the amount of surplus water, etc." (Egbert's *Hygiene and Sanitation.*)

4. Disease germs must first effect an entrance into the body; they then grow, multiply, and produce toxic substances which are absorbed and distributed throughout the system. Sometimes purely local effects are produced, such as the plugging up of small vessels or causing changes in the cells and tissues. Occasionally, as in anthrax, the disease germs invade the various tissues, and cause disturbances more by their presence and multiplication than by their toxic products.

5. The inspection should include:—the color, reaction, specific gravity, sediment, taste, odor, total quantity of solids and of water; the percentage of cream, fats, lactose, casein, and ash; the presence or absence of preservatives, coloring matter, added solids, and dilution. There should also be thorough investigation as to its source, the cows and their environment, the method employed in caring for, milking, storing and transporting the milk.

BACTERIOLOGY.

1. Bacteria are classified as:—1. Cocci; 2. Bacilli; and 3. Spirilla.

Saprophytes are bacteria that derive their nutriment from dead organic substances; *Parasites* derive their nutriment from **living tissues.**

2. "A *ptomain* is a basic substance, contains nitrogen, is found in putrefaction of proteid matter, and resembles alkaloids in its action, combining with acids to form salts; at one time considered the essential element in bacterial intoxication. *Toxins* are formed by most all pathogenic bacteria, both by analysis and synthesis, in the living organism; do not act like basic bodies, cause symptoms like animal and plant alkaloids (snake venom, abrin, strychnin), and vary with the source, each kind of bacteria having its own specific toxin; their effect on the human organism is immense in minutest dosage, not only constitutionally but also locally to less degree" (Thayer's *Pathology*).

Common sources of ptomain poisoning are:—putrid fish, meat, sausages, cheese, milk, and ice-cream.

5. The presence of *Bacillus coli communis* indicates the possibility of any organic contamination. Therefore the finding of this one bacillus, with or without any pathogenic bacteria is evidence of the contamination of the water. It is difficult to make an accurate estimate of the relative values of a chemical and a bacteriological analysis of water. Both methods are necessary, neither method is infallible, and each may help the other. Water may be pure from a bacteriological standpoint and yet the chemical analysis may show that it should be condemned. The chemical analysis is probably the more valuable to decide as to the quality of a drinking mater.

SURGERY.

1. *Toxins* are poisonous products of bacteria See answer to No. 2 in Bacteriology, above).

Antitoxins are substances elaborated in a living body to counteract the poisonous effects of toxins.

Phagocytes are cells that devour and destroy microorganisms.

5. Both conditions are characterized by sudden onset, pain, tenderness, rise of temperature, and rapid pulse. But *appendicitis* will be accompanied by history of intestinal disorders, rigidity of abdominal muscles, chiefly the right rectus, possibly vomiting and constipation, the right iliac fossa is the site of the pain and tenderness; in *acute ovaritis* there will probably be some menstrual disorder, the ovary will be tender on pressure, and unless there are adhesions it is mobile, the tenderness and pain are nearer the median line, there is generally either salpingitis, endometritis, gonorrhea, or septic infection. In case of doubt an exploratory incision will clear up the difficulty.

7. (1) *Talipes varus*, in which the inner edge of the foot is drawn up, the anterior two-thirds is twisted inwards, and the outer edge rests on the ground.

(2) *Talipes valgus*, in which the outer edge of the foot is drawn upwards, and the inner side of the foot and ankle rest on the ground. This condition is the reverse of *talipes varus*.

(3) *Talipes equinus*, in which the heel is raised and cannot be brought to the ground, and the patient walks on the toes and on the distal ends of the metatarsal bones.

(4) *Talipes calcaneus*, in which the toes are raised and the heel depressed, so that the patient walks on the latter. This condition is the reverse of *talipes equinus*

OBSTETRICS.

5. A baby one week old should be nursed at the mother's breast regularly every two hours between the hours of 5 A.M. and 11 P.M. It should receive about an ounce or an ounce and a half at each nursing.

6. Uterine inertia, pelvic deformity, persistent posterior position of the occiput, eclampsia, face presentations, arrest of the after-coming head in breech cases, hemorrhage.

8. During pregnancy the patient should be put in as good a physical condition as possible; the uterus should not be emptied too rapidly; the patient should not be allowed to become exhausted; after the birth of the child the fundus of the uterus should be grasped and held till the placenta is expelled; after the expulsion of the placenta the patient should receive a dram of the fluid extract of ergot, and an abdominal binder should be applied. The physician should not leave till at least an hour after the conclusion of the labor, and not even then if the patient's pulse is too or over.

GYNECOLOGY.

4. (1) The least suspicion of even the possibility of pregnancy; (2) menstruation; (3) acute endometritis; (4) malignant disease of the uterus or vagina; (5) acute pelvic inflammation.

LEGAL MEDICINE

1. A *medicine* is anything that possesses or is supposed to possess remedial properties.

A *poison* is any substance which, on being in solution in the blood, may produce death or serious bodily harm.

3. Malpractice is a failure on the part of a medical practitioner to use such skill, care and judgment in the treatment of a patient as the law requires; and thereby the patient suffers damage. If due to negligence only, it is *civil* malpractice. But if done deliberately, or wrongfully,

or if gross carelessness or neglect has been shown, or if some illegal operation (such as criminal abortion) be performed, it is *criminal malpractice*.

BULLETIN OF APPROACHING EXAMINATIONS.†

STATE.	NAME AND ADDRESS OF SECRETARY.	PLACE AND DATE OF NEXT EXAMINATION.	
Alabama*	W. H. Sanders, Montgomery	Montgomery	April 1–6
Arizona*	Ancil Martin, Phoenix	Phoenix	April 1
Arkansas*	F. T. Murphy, Brinkley	Little Rock	April 9
California	Chas. L. Tisdale, Alameda	San Francisco	April 16
Colorado	S. D. Van Meter, 1723 Tremont Street, Denver	Denver	April 2
Connecticut*	Chas. A. Tuttle New Haven	New Haven	March 12
Delaware	J. H. Wilson, Dover	Dover	June 18
Dis. of Col'bia	W. C. Woodward, Washington	Washington	April 11
Florida*	J. D. Fernandez, Jacksonville	Jacksonville	May 15
Georgia	E. R. Anthony, Griffin	Atlanta	April —
Idaho	J. L. Conant, Jr., Genesee	Boise	April 2
Illinois	J. A. Egan, Springfield	Chicago	April 17
Indiana	W. T. Gott, 120 State House, Indianapolis	Indianapolis	May 28
Iowa	J. F. Kennedy, Des Moines	Des Moines	March 19
Kansas	T. E. Raines, Concordia	Topeka	June 11
Kentucky*	J. N. McCormack, Bowling Green	Louisville	April 23
Louisiana	P. A. La Rue, 211 Camp St., New Orleans	New Orleans	May 9
Maine	Wm. J. Maybury, Saco	Portland	March 5
Maryland	J. McP. Scott, Hagerstown	Baltimore	June —
Massachusetts*	E. B. Harvey, State House, Boston	Boston	March 12
Michigan	B. D. Harison, 205 Whitney Building, Detroit	Ann Arbor	June 11
Minnesota	O. E. Linjer, 24 South Fourth Street, Minneapolis	St. Paul	April 2
Mississippi	J. F. Hunter, Jackson	Jackson	May 14
Missouri	J. A. B. Adcock, Warrensburg	St. Louis / Kansas City	April 16
Montana*	Wm. C. Riddell, Helena	Helena	April —
Nebraska	Geo. H. Brash, Beatrice	Lincoln	
Nevada	S. L. Lee, Carson City	Carson City	May 6
N. Hamp're*	Henry C. Morrison, State Library, Concord	Concord	July 9
New Jersey	J. W. Bennett, Long Branch	Trenton	June 18
New Mexico	B. D Black, Las Vegas	Santa Fe	June 3
New York	C. F. Wheelock Univ. of State of New York, Albany	New York, Albany, Syracuse, Buffalo.	May 21
N. Carolina*	G. T. Sikes, Grissom	Morehead City	May —
N. Dakota	H. M. Wheeler, Grand Forks	Grand Forks	April 2
Ohio	Geo. H. Matson, Columbus	Columbus	June 11
Oklahoma*	J. W. Baker, Enid	Guthrie	March 26
Oregon*	B. E. Miller, Portland	Portland	April —
Pennsylvania	N. C. Schaeffer, Harrisburg	Philadelphia / Pittsburg,	June —
Rhode Island	G. T Swarts, Providence	Providence	April 4
S. Carolina	W. H. Lester, Columbia	Columbia	June —
S. Dakota	H. E. McNutt, Aberdeen	Sioux Falls	July 10
Tennessee*	T. J Happel, Trenton	Memphis, Nashville, Knoxville,	May —
Texas	T. T. Jackson, San Antonio	Austin	April 30
Utah*	R. W. Fisher, Salt Lake City	Salt Lake City	April 1
Vermont	W Scott Nay, Underhill	Burlington	July 9
Virginia	R. S Martin, Stuart	Lynchburg	June 18
Washington*	C. W. Sharples, Seattle	Seattle	July 2
W. Virginia*	H. A. Barbee, Point Pleasant	Wheeling	April 9
Wisconsin	J. V. Stevens, Jefferson	Madison	July 9
Wyoming	S. B. Miller, Laramie	Cheyenne	

*No reciprocity recognized by these States.
†Applicants should in every case write to the secretary for latest details regarding the examination in any particular State

REQUIREMENTS FOR MEDICAL LICENSURE.

In the following table the States requiring of the candidate both a diploma from a recognized college and an examination are printed in roman; those requiring either a diploma or an examination, in italics; those requiring an examination only, in small capitals

STATE	FEE	STATE	FEE
ALABAMA	$10.00	Nebraska	$25.00
Arizona	10.00	Nevada	25.00
ARKANSAS	10 00	New Hampshire	10 00
California	20.00	New Jersey	25.00
Colorado	25.00	*New Mexico*	25 00
Connecticut	15.00	New York	25.00
Delaware	10.00	North Carolina	10 00
District of Columbia	10 00	North Dakota	20.00
Florida	15.00	Ohio	25 00
Georgia	10.00	Oklahoma	5 00
Idaho	25.00	OREGON	10 00
Illinois	10.00	Pennsylvania	25.00
Indiana	25 00	RHODE ISLAND	10 00
Iowa	10.00	South Carolina	10 00
Kansas	15.00	South Dakota	20.00
Kentucky	10.00	TENNESSEE	10 00
Louisiana	10.00	TEXAS	15.00
Maine	10.00	Utah	25 00
Maryland	15.00	Vermont	15.00
MASSACHUSETTS	20.00	Virginia	10.00
Michigan	25.00	Washington	25 00
Minnesota	10.00	WEST VIRGINIA	25 00
MISSISSIPPI	10.00	Wisconsin	10 00
MISSOURI	15.00	Wyoming	25 00
Montana	15.00		

Wisconsin.—The State Board of Medical Examiners is actively enforcing the medical laws of the State. Warrants have been issued for the arrest of several illegal practitioners, some with fake diplomas, and some who indulge in indecent quack advertising.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious disease reported to the Sanitary Bureau, Health Department, New York City, for the week ending February 23, 1907:

	Cases	Deaths
Tuberculosis Pulmonalis	360	220
Diphtheria	277	46
Measles	259	10
Scarlet Fever	298	13
Smallpox	1	—
Varicella	76	1
Typhoid Fever	45	12
Whooping Cough	66	5
Cerebrospinal Meningitis	13	12
Malarial Fever	. .	. .
Totals	1395	319

Verminous Appendicitis.—Ragaine believes that the presence of worms in the intestine may become the immediate cause of appendicitis. These parasites provoke an ulceration of the mucosa of the cecum, thus opening a portal of entry for infection. Search should be made in a case of appendicitis for the possible presence of intestinal worms. The physician could often discover the presence of ascaris, trichocephalus, or oxyuris. This would be a most valuable indication. Appendicitis of verminous origin may sometimes be cured by the expulsion of parasites alone.—*La Presse Médicale.*

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine-Hospital Service, during the week ended February 22, 1907:

SMALLPOX—UNITED STATES.

		CASES.	DEATHS
Florida, Lakeland	Jan. 26–Feb 2	6	
"	Feb. 9–16	3	.

THE SALT-FREE DIET IN CHRONIC PARENCHYMATOUS NEPHRITIS.*

By GEORGE L. PEABODY, M.D.,

NEW YORK

The benefit to be derived from the administration of food containing only a minimum of sodium chloride in cases of anasarca due to parenchymatous nephritis seems to have been independently discovered by several observers. My purpose in drawing attention to it to-night is to ask its trial in a condition which is always distressing and which, by other means, is often rebellious to treatment.

The literature on the subject, which dates only a few years back, is not voluminous, but almost all who have published accounts of systematic trial of the method have been astonished at the good results which have attended their efforts in properly selected cases. In this country attention has been called to it by A. O. J. Kelly and Charles A. Fife of Philadelphia, and Joseph L. Miller of Chicago.[1] Miller gives references to the bibliography. Since the date of these papers (1905) not very much has been written upon it.

In opposition to most writers, Ferramini[2] considers that salt is often beneficial in "kidney diseases," and that its withdrawal is nonsense, although he admits that its administration is often followed by a temporary increase in the albumin and in the kidney elements in the urine.

Rumpf[3] undertook to throw light on the etiological relation of salt-retention in nephritis by ascertaining by chemical analysis whether in various organs salt is present in undue amount after death; and also whether pericardial, pleural, and peritoneal fluids contained an undue amount of salt in the cases of kidney disease that he examined. He did not confine his investigations to cases of parenchymatous nephritis, however, but used the material from all sorts of cases of nephritis.

He found (*a*) that in adults in many cases the salt content of the kidneys exceeded that of the blood and other organs, (*b*) in many cases the salt content of the blood and tissues was increased in amount beyond the normal; (*c*) the pericardial, pleural, and peritoneal fluids showed no uniformity in their salt content, and (*d*) the peritoneal fluid in cases other than nephritis often showed a high salt content.

Widal[4] was one of the earliest observers to advocate a salt-free diet in this form of nephritis, and in a recent article read before the seventh French congress for medicine, he repeats his views and gives his later experience. He considers the object of the treatment to be twofold: to free the system as much as possible from salt, and therefore from water; and when this has been accomplished to bring about a balance between the salt in the body and the permeability of the kidneys for salt. He believes that the patient's food should contain only the natural amount of salt, *i.e.* that none should be added artificially by either cook or patient. In this way the patient will take only about one and a half grams a day.

My experience accords with his, that in many cases, very soon after the beginning of the treatment, edema, and therefore body weight, will diminish rapidly. This occurs more promptly and more completely if the patient remain absolutely at rest in bed. In some cases edema of the lower extremities does not entirely disappear, and in these diuretics must be employed. In general, he says, the effect is much more marked in parenchymatous than in interstitial nephritis. I have had scarcely any success with well marked interstitial cases.

In some cases of parenchymatous nephritis, after the edema had disappeared, he allowed patients to take a little salt, even as much as five, eight, or ten grams a day, if urinary analysis showed that it was all excreted. In my experience, a return to an ordinary diet is likely to be followed by a recurrence of edema.

It seems to be doubtful if diaphoretics are of much assistance, for in removing water they remove but little salt. Saline purgatives remove salt as well as water, but they cannot be used with sufficient frequency to be of much assistance. Widal thinks that some diuretics are of material help in removing the salt, especially the cardiac diuretics, inasmuch as the arterial tension is often low. Widal and Javal found squill of little use. Potassium acetate was better, but very uncertain. Digitalis alone was often of no value, and of course was contraindicated if the tension were high. When this was low theobromin alone or associated with digitalis was often of great assistance.

Boyd[5] in Edinburgh noticed that a patient with general anascarca conceived a violent dislike of foods containing salt, and upon following his inclination in this matter he was surprised to find a marked diminution in his edema. Boyd's attention was attracted to the subject in the literature, and he subjected a patient suffering from diffuse nephritis with anasarca to the influence of salt-free diet. Besides the anasarca, his patient had serious effusions in both pleural cavities and the peritoneum. All his food was prepared without salt, and his fluids were restricted. In two days improvement was noted. His urine became doubled in amount and he eliminated large quantities of chlorides. The diuresis continued until all edema had disappeared. In this case a patient who had been edematous for years lost all edema in seventeen days.

Miller[1] discusses the rationale of the condition and then records his own experience. He notes that Widal and Javal[6] have "called attention to the inability of many nephritics to eliminate sodium chlorid in a normal manner. The salt retained in the tissues required a certain amount of water to main-

*Read at a meeting of the Practitioners' Society of New York, on Friday, February 1, 1907.

tain it in the proper molecular concentration, thus leading to edema, and he suggests this as the probable explanation of dropsy in nephritis. This chlorid retention was found chiefly in acute and chronic parenchymatous nephritis, and especially in patients who were edematous. The retention was not found in the interstitial form, and we know that edema, when it develops in these cases, is usually of cardiac origin. They, furthermore, decided that the impermeability of the kidney to urea and salts did not necessarily go hand in hand, as in the terminal period of Bright's disease there may be marked retention of chlorids, but none of urea, phosphates, or sulphates. They report a case of uremia with daily elimination of 28 grams of urea, but only 0.39 gram of sodium chlorid. For this reason they consider the chlorid elimination as a better index of the functioning power of the kidney than the excretion of urea, and that the unfavorable prognosis of a case is associated with reduced chlorid elimination."

To quote from another part of Miller's paper: "Only small amounts of sodium chloride are essential for the animal economy. According to Bunge, a person upon a mixed diet requires daily 1 or 2 grams; most people, however, consume 10 or 20 grams. The excess of chlorid is eliminated chiefly through the kidneys."

The feces and skin eliminate relatively very small amounts. The daily elimination of sodium chloride varies widely under unchanged circumstances in the same individual without apparent cause.

If salt is increased in amount in the food of patients suffering from chronic parenchymatous nephritis, edema develops or increases, albumin in the urine increases, headache, nausea, and stupor may develop. "Widal and Javal were able to make the edema appear and disappear at will by increasing or withdrawing the chlorides."[1]

Numerous investigators have confirmed and amplified these statements, and it has been shown that sodium chloride, however administered, whether in food or subcutaneously, or by enema, is capable very clearly of inducing or aggravating many of the symptoms of these patients.

Patients can become more edematous without any increase in the intake of fluids or any diminution in the elimination of water by other channels, particularly by the skin.

Miller's conclusions are as follows: "In patients with moderately severe nephritis associated with edema, the ingestion of large amounts of sodium chlorid is followed by chloride retention. The patient gains in weight, the edema becomes more marked, the albuminuria increases, and symptoms may develop resembling uremia.

"In patients with very severe nephritis, and especially those with uremia, chlorid retention is very marked, as scarcely any of the extra chlorids administered is eliminated.

"Individuals with apparently healthy kidneys, following the ingestion of sodium chlorid, there is a chloride retention equal to that of mild nephritis. The individual gains in weight, but there is no visible edema, no albuminuria, and no uremic symptoms."

A year later than the paper by Widal and Javal[7] quoted by Miller, they showed that in a case of small, contracted kidney albuminuria could be increased or diminished uniformly by increasing or diminishing the amount of sodium chloride in the food. They concluded that the albumin in the urine was entirely uninfluenced by the albumin in the food, as has long been believed.

It has been suggested[8] that an explanation of the belief of many clinicians that in cases of kidney disease white meats are better borne than dark meats, is to be found in the habit of using more salt in the preparation of the dark meats than in the light ones.

Interesting in connection with the general subject of this paper is a case of persistent edema in an otherwise healthy person who had acquired the habit of eating salt inordinately. This case is reported in the *Practitioner* by S. H. Bryant.[9] The patient was a physician, forty years of age, who sought medical advice on account of persistent edema of the feet and legs, fearing that he had kidney or heart disease. He had never been ill before, but had noticed trifling varicose veins which had never caused any trouble. Shortly before he sought medical advice he noticed, in addition to his edema, a feeling of weight in his legs and a sense of undue fatigue on slight exertion. Careful examination showed his organs to be sound, especially his heart and kidneys. Inquiry into his habits showed an inordinate fondness for salt, which he added even to salt meat and salt fish, and he confessed to the habit of completely emptying the saltcellar twice a day at his two principal meals. His urine contained nearly three times as much sodium chloride as normal, and had a specific gravity of 1.028. It cost him much effort to abandon his salt, but in two weeks the edema had perceptibly diminished, and in three weeks it had disappeared. He was not weighed, but he felt that he had lost weight as he lost edema.

My colleagues in the New York Hospital, Drs. S. W. Lambert and L. A. Conner, and myself have tried the effect of the salt-free diet as a means of removing fluid in cases of anasarka of various kinds, and I am much indebted to their efforts for experience and for clinical material in this subject, and we have all been greatly aided by the careful observation of the cases, as well as by the full and accurate notes made by a very efficient resident staff, and especially by the house physicians, Drs. Edward Cussler and Frederick H. Bartlett. In anasarca due to heart causes or to combined failure of heart power and interstitial nephritis, I have accomplished very little with it. Although the statement has been made that it causes a lowering of blood pressure in high tension with arteriosclerosis,[10] such has not been my experience. The results of carefully conducted observations in cases of this class have been almost uniformly disappointing in my wards. The diet is not unpalatable, and can be made sufficiently varied to be well borne for weeks if necessary, though ordinarily a few days will suffice to remove the edema, or greatly to diminish it.

Unsalted bread is very palatable, especially if made with milk instead of water. Made in this way, it does not become hard or dry, if not too long kept. The bread that I show you this evening was made with water and is several days old, and, except on the surface, is not dry or hard.

It will be observed that the expression "salt-free" is not literally correct. Most of the articles that enter into the diet contain the small amount of salt with which nature has supplied them. This is merely intended to convey the idea that no salt is artificially added to the food. We have usually made some attempt at the same time to limit the quantity of fluids ingested, but it is not necessary to carry this part of the plan to the extent of making the patient uncomfortable. The daily bill of fare admits of great variety. We have generally found the following sufficient:

Breakfast.—Coffee or tea, eggs, cereals, cream, fresh butter, fruits, bread made without salt.

10 A.M.—A glass of milk.

Dinner.—Chicken, fish, potato variously prepared, bread made without salt, ice cream, jelly, fresh butter, cocoa ℥viii.

3 P.M.—A glass of milk or water.

Supper.—Eggs, chicken, bread without salt, jelly, custard, cream, fresh butter, tea ℥viii.

8 P.M.—A glass of milk or water.

Almost any kind of meat or vegetable can be given to which salt is not added. I wish again to emphasize the fact that it is especially in cases of general anasarca from chronic parenchymatous nephritis, with failing heart power, that it is to be highly recommended. In many of these cases its effect is perhaps enhanced by the simultaneous administration of heart tonics. Of these I have chiefly used digitalis and theobromin. Of these two theobromin, in the form of diuretin, is perhaps to be preferred, but careful observation in my cases justifies the belief that they really did not contribute to the relief of the patients, for they raised blood pressure in none of them. In some cases its operation is facilitated and aided by stimulating elimination by the skin by hot packs given every other day, although, as I have already said, but little chloride is thus disposed of. In some cases we have called to our aid irrigation of the colon by hot water, to which sodium bicarbonate, half an ounce to the pint, has been added, instead of the more usual chloride, which is omitted for obvious reasons. It is important to raise the density of the water used for colon irrigation by some such indifferent agent, because water alone is irritating to the mucous membrane. Catharsis helps in some cases, for which purpose the compound jalap powder has been much used, but I am convinced that the most important agent is the negative one of which I am writing; and in some cases, without other aid, it will cause a rapid disappearance of edema.

After complete removal of the edema I am now administering progressively increasing daily quantities of salt to these patients, carefully watching for any recurrence of this symptom, the endeavor being to ascertain for each patient what his salt equilibrium may be, but I am not yet prepared to report results of these observations.

By far the best way of ascertaining the exact amount of water lost by such a patient is by weighing him. Measurement of the circumference of his abdomen and of his extremities is of little relative value. Unless some other illness supervenes, he loses no weight except water, for he is very well nourished by the food that he takes, so that by weighing him we have a fairly exact means of ascertaining the result that we are bringing about.

The change in his appearance is usually very striking. In a few days a patient whose eyes were almost closed by facial edema often shows no puffiness of the face at all.

It is of interest that the disappearance of edema is not always accompanied by any very obvious increase in the amount of urine passed, though this sometimes also happens. He must lose water in other ways, and he often loses both salt and water by the bowel.

Case I.—William C, age 24, a carpenter, entered the hospital August 3, 1906. He had edema of the legs and scrotum, and penis, besides a large amount of fluid in his left chest. His urine was of high specific gravity, and contained a large amount of albumin and hyaline, and granular casts. His blood pressure was low and continued so, from 100 to 120 mm., as a rule.

Under cardiac stimulation by digitalis, or diuretin, colon irrigation by salt solution, to which potassium iodide and purgation were added, his edema fluctuated in amount, and finally returned, and fluid accumulated in both sides of his chest and his abdomen, necessitating frequent tapping of the chest. On one occasion two quarts of fluid were withdrawn from his abdomen.

Up to the 14th of September, 8,850 c.c. of fluid were mechanically withdrawn from his serous cavities, and dyspnea had become urgent. He was then put upon the salt-free diet, and his fluids were restricted to between 40 and 50 ounces a day. His weight at this time was 160 pounds, in spite of the fact that within the previous seven days 3,150 c.c. of serum had been withdrawn from his cavities, or a little over six pounds in weight.

He had been six weeks under the usual treatment of the condition without any but transitory improvement in his symptoms. During these six weeks 16 pounds of fluid in all were mechanically removed from his cavities. After the salt-free diet was commenced his chest required only two tappings, by which 4 pounds of fluid were withdrawn; and then, coinciding with the rapid disappearance of edema, there was no recurrence of fluid in any of his cavities. Under this diet he lost in twenty days 32 pounds in weight, which I believe it fair to consider 32 pounds of fluid; he felt well, looked like a different man, was up and about all day, and left the hospital on the 8th of October without any appearance of edema, and weighing 128 pounds as compared with 160 pounds three weeks previously.

In him blood pressure seemed to be uninfluenced by any treatment to which he was subjected, and this accords with the fact that he was only little improved by cardiac stimulants and the other therapeutic efforts until the salt-free diet was tried. The results following upon this fact would seem to justify the assumption that it was the chief cause of his recovery.

Case II.—Was an Italian, Antonio G., a gilder by occupation, 40 years of age. He entered the hospital on the 27th of July with fluid in both chests and the abdominal cavity, and edema, which was especially marked in the abdominal wall, genitals and lower extremities.

His urine, 28 ounces on admission, always contained albumin. Before the salt-free diet was commenced this reached the amount of .6 per cent.; hyaline and granular casts were abundant, and its specific gravity fluctuated between 1,008 and 1,025. His blood pressure was not uniform, but fluctuated, without obvious cause, between limits as wide as 140 and 210 mm., and when high it failed to respond to the dilators. Under symptomatic treatment which was intelligently tried for seven weeks, the edema was at times diminished in amount, but it always returned to the original extent when he was allowed to get up. Headache was very troublesome throughout this period.

The salt-free diet with restriction of fluids was tried from the 15th of September to the 8th of October, when he left the hospital greatly improved. In these three weeks he lost 22 pounds in weight, his headache and dyspnea disappeared, all the fluid left his serous cavities without tapping, and the edema vanished. In this case the urine became and remained higher in amount than it had been under symptomatic treatment, its fluctuation being between 35 and 71 ounces.

The hot pack was used throughout his treatment, and in it he perspired freely; but, as in the last case, no complete alleviation of symptoms took place until the salt was withdrawn from his food.

Case III.—Another, Antonio G., a Spaniard, a

cook by occupation, 39 years of age, was admitted on November 30, 1906. He had been twice in the hospital before, and we knew him well. His urine contained .3 per cent. albumin and hyaline and granular casts, and had a specific gravity of 1,018, and he was passing 57 ounces. The last time he was in the hospital he was discharged improved on November 14, 1906, with the diagnosis chronic nephritis, chronic myocarditis, and dilatation of the heart, and cirrhosis of the liver.

His distress was great on his readmission, and was sufficiently accounted for by the presence of fluid in both pleural cavities and abdomen, as well as by edema in his arms, abdominal wall, genitals, and lower extremities. His blood pressure was 126 mm. He was at once put upon a salt-free diet, together with a mixture containing in each dose two minims of the fluid extract of digitalis, twenty of the fluid extract of convallaria, and five grains of potassium iodide. At first he was too ill to be able to stand on the scales for the purpose of being weighed, but after three days of treatment he weighed 147 pounds. In four days the improvement in his general appearance was very obvious, and in ten days his edema was practically all gone, and he had lost fifteen pounds in weight. He was then up and about the ward without any return of it for five days more, when he felt so well he went to his work.

His blood pressure was not raised by the treatment, and was usually below the level recorded on his admission, fluctuating generally between 90 and 110 mm. His urine increased from 57 ounces to 72 ounces a day as the edema left him.

He told us that his weight of 132 pounds, which he reached on the tenth day of treatment, was his normal weight.

Case IV.—Andrew K., a laborer, a native of Austria, 20 years of age, was admitted on October 5, and remained until December 10, 1906.

He was suffering from chronic parenchymatous nephritis with anasarka and double hydrothorax and ascites. On admission his entire body from his eyes down was edematous, his genitals being especially so. His urine was of low gravity and contained .9 per cent. albumin and hyaline, granular and epithelial casts, some blood cells, and some pus. His blood pressure was 130 mm. on admission, and it usually fluctuated between that and 160 during his treatment, except during the occurrence of an attack of colitis, when it fell to 100, and remained between that and 110 for twelve days.

His case is of unusual interest, because while under treatment, and while showing marked improvement in the extent of anasarka, he developed an acute and severe colitis. Before this occurred he had lost 51 pounds of fluid, his weight having fallen from 215 pounds to 164 pounds in about six weeks. During this time the improvement in all of his worst symptoms was very marked, in spite of the fact that he developed incidentally acute pleurisy and pericarditis. During the colitis his diet was necessarily changed, and salt was not withheld. At first, after this change, he continued to lose weight—what we might call "good" weight as distinguished from fluid—and his nutrition suffered severely. He lost thus sixteen pounds which he could ill afford. During his convalescence from the colitis on an invalid diet from which salt was not excluded, he gained twenty-three and a half pounds, and again showed evidences of considerable anasarka. When he had completely recovered from his colitis, the salt-free diet was resumed, and he sustained a loss of weight in two weeks of twelve pounds. His total net reduction in weight was thus fifty-five pounds. This was not all due to his diet, for the reason that his chests required frequent tapping, and thus large amounts of fluid were withdrawn; but until the influence of the diet was felt the fluid thus removed reaccumulated rapidly. Besides this, it must be said that, in this case as in most of the others, reliance was not placed on the diet as the sole means of treatment, for hot packs, colon irrigation with hot sodium bicarbonate solution, and purging with compound jalap powder were all resorted to. As the result of it all, his edema disappeared, and the fluid ceased to recur in his chests, and he held the ground that he had gained, although allowed to be up and dressed and about the ward. On his discharge he declared that he felt better than he had for months. The amount of his urine fluctuated very widely, between 33 ounces on admission and 152 ounces after his convalescence from colitis.

Case V.—One of our most striking cases was Joe L., a boy nine years of age, whose kidneys had been decapsulated four times in the preceding two years to aid in the removal of general anasarka which was always associated with almost complete suppression of urine. On each of these occasions the result had been satisfactory, though it was in part due to other means besides the operation, such as hot packs and cardiac stimulation.

His original kidney trouble was a parenchymatous lesion following scarlatina. On this latest occasion, it was concluded to try, instead of surgery, the salt-free diet with colon irrigation and hot packs, as well as cardiac stimulation. It was found by trial that he did much better on this combination than he did when treatment was confined to the diet alone. In a month he lost twelve pounds, which was about 20 per cent. of his total weight. His abdomen contained a large amount of water when treatment was begun. This entirely disappeared without tapping and its circumference diminished by five inches.

Inasmuch as he was a growing boy of nine years, and inasmuch as he visibly increased in height during the two and a half months that he was under observation, his total loss of twelve pounds, or 20 per cent. of his body weight, is probably really much larger than it would appear to be from the figures.

From a pitiably quiet, somnolent, dull boy, who could hardly open his eyes at all on account of facial edema, he became as bright and talkative, and active as any child in the ward. His urine increased from 5, 10, and 15 ounces just after his admission to 35, 40, and 50 ounces as his treatment progressed. On former occasions decapsulation was always finally resorted to after failure to relieve him by all the other means to which resort was had on this occasion, except the diet, and it seems fair to assume, therefore, that on this occasion the diet replaced the surgical procedure which had become usual with him. In other children the effect has been more marked and more prompt.

Case VI.—John R., age 10, was admitted on the 4th of January, 1907. Five months previously, without known exposure to any of the exanthemata, he began to grow weak, pale, and short of breath. One month before admission his ankles began to swell, and soon thereafter his face, eyelids, all of his extremities, the skin of chest and abdomen, as well as of his genitals, became much swollen. His parents brought him to the hospital on account of the general anasarca and dyspnea. Besides fluid in the subcutaneous tissues, it was found on examination that there was fluid also in his abdomen and his right chest. His blood pressure was 100 mm., and it did not vary materially from that level. His urine contained a considerable quantity of albumin, and hya-

line and granular casts. He passed during the first two days 9 and 16 ounces, respectively. His weight on admission was 65½ pounds. He was put upon a salt-free diet, colon irrigation, and, every other day, hot packs. Diuretin, digitalis, and strychnine were given at different times, but it is very doubtful if they were of any assistance, for the blood pressure did not vary appreciably while they were taken.

A few days after his admission 600 c.c. of fluid were withdrawn from right chest by aspiration.

The fluid did not recur in his chest and disappeared from his abdomen, and in less than two weeks his anasarca had completely disappeared, his color had improved, he felt bright and well, and was allowed to use a wheel chair, and then to walk about. His urine increased in amount from 9 to 20, 30, 40, and as a maximum 51 ounces.

His kidney condition, of course, is not cured, but his edema has entirely disappeared, and though somewhat pale he looks like a well boy.

CASE VII.—Lucy P., age 5 years, was admitted on January 9, 1907. She was perfectly well until six months ago. Her father is a telephone operator in a hospital for the exanthemata, and, though she is not known to have had any illness since her babyhood, one must suspect the possibility of her having contracted one of the exanthemata without its having been recognized.

Six months before her admission she began to complain of abdominal pains, and then soon after, puffiness of the eyes was noticed, and later her ankles and legs, and abdomen had become swollen. Of late she had been passing only a small amount of urine.

On admission she presented all of the evidences of anasarca noted above. Her eyes were almost closed; her abdomen contained a small amount of fluid, but not enough to give a fluid wave on percussion. Her urine could not be measured, as it was in part passed involuntarily, but it was clearly small in quantity. It contained a considerable quantity of albumin, and hyaline and granular casts. Blood pressure was 105 mm.; weight was 36 pounds.

Treatment, which was begun at once, consisted in salt-free diet, diuretin, hot pack every second day, colon irrigation, and small doses of compound jalap powder.

Improvement began on the second day, and by the eighth day the edema had entirely gone, and her general condition was correspondingly improved. She was allowed to get up and play about the ward with the other children, and left the hospital on the fourteenth day, looking apparently well, although her kidney lesion of course persisted.

Appendicostomy.—Drawing the appendix out through a laparotomy incision and fixing it in this position after cutting off its tip has already been found of great service for the purpose of performing irrigation of the colon in cases of obstinate colitis, but Gil suggests that by this means intestinal distention of a serious grade may be combated, and also that rectal artificial feeding can be more effectively carried on through the appendix than through the rectum.—*Revista de Medicina y Cirujia de Madrid.*

INFLUENZA; MASTOID ABSCESS; LEPTOMENINGITIS; NINE-DAY UNCONSCIOUSNESS; THREE OPERATIONS; DEATH; AUTOPSY.*

BY H. BROOKER MILLS, M.D.,
PHILADELPHIA,
ASSISTANT PEDIATRICIAN TO THE PHILADELPHIA HOSPITAL.
AND
NATHAN G. WARD, M.D.,
PHILADELPHIA,
CLINICAL PROFESSOR OF LARYNGOLOGY AND OTOLOGY IN THE MEDICAL DEPARTMENT OF TEMPLE COLLEGE; LARYNGOLOGIST AND OTOLOGIST TO ST. AGNES HOSPITAL; LARYNGOLOGIST AND OTOLOGIST TO THE SAMARITAN HOSPITAL.

THE points of especial interest in the case we are about to report are the following: Attack of influenza, followed by mastoid abscess; suppuration and necrosis of the ethmoid; relief of symptoms, except headache, following operation; sudden development of violent pain in the head; unconsciousness for nine days; restlessness; high remittent temperature; no palsies or other localizing symptoms; purulent leptomeningitis; pus in the cerebral ventricles; death; autopsy.

L. J., male, thirty-nine years; foreman in a clothing manufactory, first consulted Dr. Mills May 21, 1906. For several days he had had chills, sore throat, headache, backache, and legache, but no cough, nausea, or perspiration, and no appetite; bowels open freely; temperature, 102°; pulse, 102; diagnosis, influenza. The facial expression was that of a very sick man; he was ordered to bed, and treatment prescribed. The following day he was somewhat improved and reported having had a good night, but was complaining of some aching in the right ear. The treatment was continued and hot water bag applied to the ear. The following day he complained of considerable pain on the top of the head, and excessive discharge from the right ear, which, in spite of local and constitutional treatment, continued for ten days, with a temperature and pulse each averaging about 100. Suddenly, on June 3, 1906, ptosis of the right eyelid developed, with increased headache, and Dr. Ward was called in consultation. The conditions which led to the decision for prompt mastoid operation were the ptosis of the right eyelid, the swelling of the right cheek, excessive and increased pain, radiating over the right half of the head, and persistence and increase of the enormous discharge. There was a large perforation in the posterior inferior quadrant of the tympanic membrane, but no bulging. The internal posterior wall of the canal, which forms the anterior wall of the mastoid antrum, was red and tender, but no sagging of any part of the canal. Slight edema over the mastoid and slight tenderness on deep pressure. Throughout the disease, and increased that day, there was a continued soreness over all parts of the cheek, gums, and tongue of a neuralgic character. On examination of the mouth there was not sufficient evidence to account for the pain, and as stimulation of the tympanic nerve in the tympanum caused a prickling feeling in the tip of the tongue, we attributed the soreness to the pus in the tympanum. Uranalysis made just before the operation was negative, except for an excessive amount of uric acid.

First Operation.—June 4, 1906, Dr. Ward, assisted by Dr. Carle Lee Felt, operated on the mastoid. The cortex was exceedingly thick and dense; cells small; septi resistant, the chisel was required

*Reported at a meeting of the Philadelphia County Medical Society.

to break them down, pus was found near the surface at the middle and tip; it was thick and yellow and in drops, showing recent formation. There were dark spots in various parts of the bone. No necrosis and no dead or bare bone in the antrum. The whole cancellous tissue, including the tip, was removed. The usual dressing was applied. At the close of the operation the temperature was 98.8°, pulse 124, respirations 26. At midnight the temperature was 102.6°, pulse 132, respirations 24. After a restless night, at 9 A.M. the temperature was 98.2°, pulse 112, respirations 22; June 6, the lowest temperature was 99.6°, pulse 110, respirations 24; the highest temperature was 103.6°, pulse 108, respirations 22, where it stayed with slight remissions until June 7, at 3 P.M., when the wound was dressed for the first time; in splendid condition. June 8, at 12 M., the temperature was normal, pulse 98, respirations 20; the highest for the day at 3 P.M., temperature, 102.4°; pulse, 96; respirations, 18. The wound was dressed, followed by a drop to normal on June 9, at 7 A.M. At 3 P.M. the temperature was 99.4°, pulse 110, respirations 20. June 13, at 7 A.M., the temperature was normal; at 1 P.M., 99 2-5°; pulse, 94; respirations, 18. The patient had been out of bed a part of each day after June 11; had gone to the toilet; was sleeping through the entire night and feeling comfortable. The conditions were considered favorable and the services of the nurse were dispensed with. From June 13 to 16 no temperature chart was kept; when the temperature was taken at irregular intervals, it was normal or only a fraction above. The appetite was very much improved; bowels, freely open; nights, fairly restful, and the patient was decidedly hopeful.

After increasing the amount of time out of bed each day, on June 16, at Dr. Mills' visit, the patient inquired as to how soon he could go downstairs and out of doors, and was making plans to take his family out of the city. Dr. Mills told him that he could do so the next day, if it met with the approval of Dr. Ward. In spite of the patient's good record, he wore a very anxious expression, and on close questioning admitted that he was not feeling as well as he would have one believe. At Dr. Ward's visit, four hours afterward, the patient having had a short sleep, felt much refreshed, seemed rather cheerful, and, without referring to the conversation with Dr. Mills about going out, asked when he could do so, and was told, if he felt as well the next day, he could go downstairs; but if the exertion caused much fatigue, to at once return and lie down. The wound was dressed; it was in excellent condition; no more discharge than could be accounted for by the forming granulations.

During the entire illness and, in spite of local and constitutional treatment, at no time was he apparently free from pain on the top of the head, worse during the higher temperatures and most severe during coughing or sneezing.

Sunday, June 17, at about 5 A.M., after sleeping soundly all night, the patient was awakened suddenly by a severe and excruciating pain in the head, which became unbearable. At 7 o'clock a messenger was sent to Dr. Mills' office, stating that the patient was almost insane from pain, and demanding some relief. Six tablets, each containing 1-20 of a grain of morphine, were sent, with instructions to give two every half hour until relieved. Before the messenger returned the wife had given the patient 1-4 of a grain of morphine which she found left from a previous prescription. Four of the tablets sent were given, making total of 9-20 of a grain of morphine administered by the mouth in the course of about an hour, following which the patient went into a sound sleep, from which he never awoke. Four hours later, Dr. Mills called and found the patient sleeping soundly; pupils evenly and moderately dilated; pulse rapid, regular, and strong; respirations regular and deep; skin moist; facial expression that of a man sleeping normally. The family were advised to leave the patient undisturbed until later in the day. The inability of the family to rouse the patient, together with the fact that, the day being Sunday, many relatives and friends were at the house, and, each expressing a different opinion, added to the anxiety caused by the long sleep; they became alarmed, and at 2 P.M. sent or Dr. Mills. As he could not be immediately gotten, Dr. H. N. Abbott, a nearby physician, was hurriedly sent for, and at that time, and at 6 P.M., when he was called again, the following was his opinion: "The condition of the patient was practically the same at both visits; that is, one of profound stupor, and when aroused he would at once relapse into his former condition. The pupils were normal; he was slightly feverish; respirations, somewhat hurried; circulation in the extremities not very good. Shortly before my first visit the patient experienced a severe vomiting spell, without regaining consciousness. Excluding the kidneys and considering the marked drowsiness, my opinion was that the stupor was due to the effect of the morphine, and, acting on that assumption, I recommended the administration, by mouth and per enema, of black coffee."

Dr. Mills called about 6 P.M., and finding Dr. Abbott there, a conference was held. It was believed that the sleep was the result of the morphine, and the black coffee was ordered continued. Dr. Mills returned later in the evening and found the patient still sleeping soundly. There was no indication for treatment other than that employed, which was continued. At about 11 P.M., a consultation over the telephone was held between Dr. Mills and Dr. Ward, the latter being out of the city and not accessible during the day; the treatment outlined was approved.

Monday, June 18. The patient had been in almost constant motion since midnight, requiring the closest watching by two attendants to keep him from rolling out of bed, and, on this account, a nurse was hurriedly gotten. There being no localizing symptoms, or other indications for intervention, we decided to continue the expectant treatment. At 12 M. the temperature was 102°, pulse 84, respirations 36. Especial attention is called to the fact that this and all subsequent temperatures were taken in the axilla. At 3 P.M. and at 9 P.M. the temperature was 103°, pulse 108, respirations 36. At midnight, temperature 102°, pulse 66, respirations 24. On dressing the wound granulations were found to be healthy. No swelling along the line of the internal jugulars, though both sides were equally tender; the breath was fetid; no discharge from the nostrils. Beginning, Sunday, June 17, and continuing until death, there was incontinence of urine and feces. The pupils varied frequently, but equally; sometimes dilated, at others contracted, with the greater tendency to dilatation; at all times acting together. There was no nystagmus at any time during the progress of the disease.

Tuesday, June 19, at 6 A.M., temperature 99.5°, pulse 74, respirations 20. At 1 P.M. a consultation was held between Drs. Mills, Ward, and Felt; temperature, 102°; pulse, 88; respirations, 26. The

patient resisted the examination, pulled away, and tried to get out of bed on the opposite side. He was permitted to place his feet on the floor and sit on the side of the bed, and was held in that position. Eyes, nose, and throat were examined. On attempting to use the ophthalmoscope, the light caused severe pain, the lids had to be held forcibly open, the eyes were in constant motion. It was impossible to get a view of the nerve head; the media were clear; vessels in various parts of the retina could be distinctly seen; no abnormal conditions detected. The breath was very fetid. In the right nostril the middle turbinal was swollen and edematous; pressure produced pain as compared to examination of the left nostril, which was normal. Examination indicated suppuration of the right ethmoid, and possibly involving the sphenoid sinus. When the examination was completed the patient stood up, which we permitted him to do in order to determine whether there was any incoordination or vertigo; he looked around in a vague, staring manner, as if endeavoring to locate the bed, turned, drew the covers back, crawled into bed, and lay down in the proper position; all without any apparent consciousness. There was not the least incoordination, nor did he seem to experience the slightest sensation of vertigo, although assuming the erect position comparatively suddenly and unassisted. There was no evidence of any twitchings, palsies, awkwardness in movement, or tenderness in any part of the body, although the sensory reflexes seemed exaggerated; no swelling or cord-like sensations along the line of the internal jugulars. The patient held his hand on the top of his head, as if in pain; but there was no evidence of its being increased by exertion or by pressure or tapping. It was our opinion that there were no indications for opening the skull; but, on the contrary, such a course would have been unwarranted.

Second Operation.—At 4 P.M. the patient was again etherized, and Dr. Ward, assisted by Dr. Felt, removed the anterior end of the right turbinal and opened the ethmoid. Pus and necrosed bone were found in the posterior ethmoid cells. The dead bone was removed and the curette forced back into the sphenoid. The condition of the sphenoid, as well as could be determined by the sense of touch transmitted through the probe and curette, was that the membrane was thickened and swollen; no necrosed or bare bone. A strip of iodoform gauze was inserted to facilitate drainage, and not to prevent hemorrhage and thus dam back the pus, free hemorrhage being rather desired to wash out any drops of pus that might have been left after the curettage. The mastoid wound was dressed and was in excellent condition. At 6 P.M., at the close of the operation, temperature 102.4°, pulse 137, respirations, 35. The temperature rose, and at 9 P.M. it was 104.6°, pulse 120, respirations 36. Upon coming out of the anesthetic, the restlessness again became very marked, keeping the nurse constantly going from one side of the bed to the other, not to keep the patient from getting out of bed, but to prevent him from rolling out.

June 20, at 7 A.M., temperature 102.2°, pulse 114, respirations 37; there were only slight changes during the day. During the afternoon the patient changed the position of his hand, which had been almost constantly at the vertex, to the forehead. This change was not due to weakness, as at times he would cross both hands, and rest them on the pillow above his head, as if to assume a more comfortable position. There was also noticed a modified Cheyne-Stokes breathing. The respirations declined until very weak; without a pause the cycle was terminated by one or more deep full inspirations, when the succeeding decline began. This character of breathing continued, more or less marked, until death.

June 21, at 9 A.M., temperature 102°, pulse 114, respirations 28, with only slight changes during the day. The patient showed the most rational signs of semiconsciousness that were present at any time during the sleep. He apparently recognized a relative for a moment, and, in response to questions, repeated the last word of the question. When requested by the nurse to turn over, would at first resist, but afterwards made efforts to assist her. Upon dressing the mastoid wound, the muscles at the back of the neck were rigid. Attempts to lift the head from the pillow caused much pain, a minute later the muscles had relaxed, and there was no difficulty in raising the head to apply the dressings. This was the first time that retraction of the head and muscular rigidity had been observed; it became permanent during the night, and continued throughout the remainder of the illness. The nurse noticed that considerable restlessness preceded such urination, and, after several attempts, succeeded in collecting a small quantity, which showed albumin for the first time (about one-half bulk), and, as before, a very heavy uric acid deposit; no casts nor any other abnormalities. There having been no improvement in his condition, except for the more favorable pulse and temperature, members of the family becoming more anxious at the prolonged sleep, and being disappointed that there should have been so little improvement in his mentality, following the second operation, it was decided to have the opinion of a neurologist to assist in determining the advisability or not of trephining; at least there would be the satisfaction of making sure that the opinions and treatment thus far were correct and nothing had been left undone. Dr. Luther C. Peter was called in consultation at 8.30 P.M. After a careful examination the following was his opinion:

"On examination of L. J. I find the following conditions: He is restless in the dorsal decubitus, moves extremities constantly, presses hand to head, and, from the facial expression, it is quite apparent that he is suffering from intense pain in the head. His breathing is not heavy; he lies in a semistupor, from which he can be partially aroused by talking, and by moving any part of his body, which he strongly resists, giving evidence of pain. Under close questioning he can, for a moment, comprehend and answers in monosyllables; but very quickly relapses into a semiconscious state. There are no palsies of the arms, legs, or face; but the left side of the body is more resistant to passive movement than the right. The deep reflexes are all present, more marked on the right, and increased in the upper extremities, as compared with the knee jerks. The Babinski reflex is absent. Kernig's sign, inability to flex the thigh on abdomen, with legs extended, is present, and attempts to forcibly flex the legs at right angles to the body cause pain. Touch and pain are apparently recognized. No muscular rigidity, save in the post-cervical muscles, which are in a state of spasticity. Attempts to raise the head cause the neck muscles to be held rigidly and the entire body is lifted; there is a tendency to retraction of the neck and head, when the patient is at rest; incomplete ptosis of both upper eyelids, but no other extraocular palsies; the left pupil is larger and responds more sluggishly to light; respirations irregular; an attempt at Cheyne-Stokes

breathing. The marked pain in the head, cervical rigidity, Kernig's sign, ptosis, and rapid pupillary phenomena, together with the temperature record, rapid pulse, and irregular respirations point to a basal meningitis of the middle fossa. Pus in the brain itself, if present at all, is masked by the meningeal symptoms, and in the absence of localizing symptoms, other than those of the basal meningitis, operative interference for the intracranial disease is not indicated. The diagnosis is basal meningitis, beginning possibly in the temporal lobe on the right, adjacent to the mastoid area, and a sequence or a complication of the mastoid disease."

At the time of the consultation it was agreed, in spite of the absence of indications for intracranial interference, that should the patient show no improvement or further signs of returning consciousness, at the worst it could do no harm and might be warranted in an effort to obtain relief from the pressure symptoms.

June 22. Starting at 6. P.M. on June 21, the temperature gradually rose, and at 4 P.M., on June 22, it was 104.8°, pulse 120, respirations 24. At 1 P.M. we saw the patient. It was apparent that, since the time of the consultation with Dr. Peter, he had lost considerable ground. He was more profoundly unconscious; restlessness replaced by quietness, and a continuous rise in temperature. We explained the conditions fully to the family, who strengthened our partial decision to take further surgical measures by urging that we should take any chance which seemed at all warranted, or in the least indicated. A uranalysis was made, which showed considerable phosphatic excess for the first time: albumin present, somewhat less than at the previous examination: and, also, for the first time, a large amount of indican, and an occasional finely granular tube cast. It was decided to open the frontal sinus, as all the symptoms had been referred over the distribution of the fifth nerve, and as dead bone was found in the ethmoid, although none in the sphenoid, it was thought that there might be suppuration in the frontal sinus, with perforation and extension to the meninges.

Third Operation.—At 4 P.M. the patient was etherized for the third time, and Dr. Ward, assisted by Dr. Felt, opened the frontal sinus from the anterior surface. There was free bleeding; no pus, necrosis, or bare bone; gauze drainage and dressing applied. The mastoid wound was dressed; granulations looked healthy. The drainage in the nasal cavity had been, and was, satisfactory; marked diminution in the fetor of the breath. At 6 P.M., at the close of the operation, the temperature was 103°, pulse 120, respirations 42; at midnight, temperature 100.8°, pulse 116, respirations 38.

June 23. The temperature gradually rose from midnight. At 11 A.M. it was 104.8°, pulse 144, respirations 46, followed by slight changes, until it dropped at 7 P.M. to a temperature of 102°, pulse 138, respirations 54. During the twenty-four hours following the third operation, with the exception of the pulse and temperature variations, there was little or no change in the patient's condition. He was restless throughout the night; acted as if it hurt him to swallow. This difficulty in swallowing appeared greater as the night wore on. Examination of the throat by Dr. Ward showed marked dryness, but nothing further to account for the difficulty in swallowing. Respirations, at irregular intervals, became more distinctly Cheyne-Stokes; the pain in the head and rigidity of the neck became very marked. He strongly resisted all efforts to turn him in bed. The pupils responded to bright light, but not to that of a match or candle. We discussed the advisability of lumbar puncture as a means of relieving the intracranial pressure.

At 1 P.M., according to a previous arrangement made by members of the family, Dr. Frank White, the wife's physician, met us in consultation. The history of the case in detail, together with the nurse's record and the temperature charts, were gone over with him. He was especially requested to make any criticisms of the treatment to date, and particularly to offer any suggestions for further treatment. Dr. White was inclined to lean towards more surgical interference. He felt as we did, and as members of the family had frequently expressed themselves, that almost anything for which there seemed to be the least excuse or indication was not only excusable, but warranted. When pressed, however, to designate the kind and location of further surgical procedure, particularly its nature and locality, he admitted that he felt exactly as we did, viz., that there was no positive indication for any intracranial interference.

From 7 P.M. to midnight the temperature varied, with quick changes, from 102.4° to 104.8°, pulse 120 to 132, respirations 44 to 50. The patient had several sinking spells, one of them during Dr. Mills' visit, at 9 P.M., and the nurse was instructed to report to him, by telephone, the patient's condition at 11 P.M., which she did. Dr. Mills tried to reach Dr. Ward by telephone, but could not locate him. He then called Dr. H. P. McAniff, and they visited the patient and punctured the spinal canal at the juncture of the second and third lumbar vertebræ, but even after applying suction to the needle not a drop of fluid was obtained; the operation was repeated, with no greater success. As it was evident the needle had entered the canal, the failure was attributed to the coagulated condition of the spinal fluid. The patient gave slight evidences of pain upon the insertion of the needle, but offered almost no resistance; no signs of discomfort followed the operation.

June 24 temperature varied from 102° to 104.2°, pulse from 130 to 168, respirations 46 to 67. We called at 12.30 P.M. The mastoid and frontal wounds were dressed; the latter was in excellent condition. The former for the first time showed increased discharge, which continued until death. No evidence of increased inflammation in or about the wounds. The breath was again extremely fetid; profound general depression. At that time, and also the day before, Dr. Ward noticed the right side of the face was drawn, indicating irritation of the facial nerve; in a few moments it was relaxed. During the afternoon the difficulty in swallowing grew less, and in its place, when taking nourishment, there was more or less coughing, as if it gagged him. In spite of this he took his nourishment fairly well. At 9 P.M. he was unable to swallow any food, and did not during the remainder of the illness, nourishment being given entirely by enemas, which were all retained.

June 25. Temperature varied between 102° and 103.6°, pulse 150 to 168, respirations 52 to 66. At 2 A.M. the respirations became very shallow, pulse very weak; the patient was perfectly quiet; the eyes were open during the entire night. During the early morning the patient made several attempts to clear his throat, but without apparent result. At 8 A.M. the pulse became intermittent. At 11 A.M. shallow stertorous breathing developed, which continued until death, at 3 P.M.

Autopsy.—On the evening of Monday, June 25, the date of death, an autopsy was performed, Drs.

Felt, McAniff, Abbott, Mills, and Ward being present. Unfortunately, it was not possible to locate Dr. Peter in time for him to be there.

On removing the calvarium there was nothing particularly striking about the superficial surface of the brain other than the presence of purulent leptomeningitis, the pus being diffused over the whole surface of the brain, extending down into each sulcus, more particularly noticeable over the left frontal and precentral lobes. Careful examination was made of all the venous sinuses to ascertain whether or not there had been sinus thrombosis, with entirely negative results. Upon raising the brain from the base of the skull, it was observed that the subarachnoid space was completely filled with thick, yellow pus, entirely surrounding the medulla and extending down the side of the cord as far as could be observed. The nerves and vessels appeared as if macerated by the pus surrounding them, and very little traction was needed to tear them loose; the spinal cord alone required to be cut. As permission to take away any part of the body was not obtained, histological examination of the brain structure could not be made. Coronal sections through all parts of the brain were made to determine the condition of its interior. The cortex seemed very much softened and pulpy and had the appearance of pus along the vessel sheaths. The white matter of the brain was less dense than normal. The ventricles, especially the lateral, were widely distended with thick, greenish pus, and upon section of the posterior cornua of the left lateral ventricle, the pressure of the pus contained therein pushed out the choroid body. The walls of the ventricles were softened and showed evidences of inflammation. Unfortunately no bacteriological examination was made; this would have been of particular interest, as it would have determined whether it was a pure or mixed infection. The upper end of the spinal cord, at the point of severance, was in the same softened, macerated condition as the superficial surface of the cerebrum. The medulla was softened, but to a less extent than the cerebrum or spinal cord. The cerebellum was in fairly good condition; far better than any other part of the brain. The thick pus in the meninges of the cord at once explained the failure in obtaining fluid from the lumbar puncture, it being evident that the circulation of the cerebrospinal fluid had been entirely eliminated. From the examination of the brain structures it seemed inexplicable how the man had lived during the last few days.

Upon examination of the interior of the skull no necrosed areas or perforations were found; in fact, the internal table of all parts of the skull bore a normal appearance. The frontal sinuses were normal. In the sphenoid sinuses the lining membrane was in an inflammatory condition and infiltrated, but no pus was found. The left ethmoid sinus was normal; the right ethmoid showed a certain amount of necrosis, as had been revealed at the operation. The left middle ear and mastoid were normal; in the right middle ear no necrosed spots were observed. Not being satisfied as to how the infection had extended into the cranial cavity, the top of the petrous portion of the right temporal bone was cut away, and in several parts, more marked in the region of the labyrinth, dark spots were found, varying from slight discoloration to almost black. These spots followed along the course of the facial and auditory nerves, determining the fact that that intracranial invasion had been an extravasation along the sheaths of these nerves and the lymphatics. This would seem to justify Macewen's observations that infiltration along the sheaths of the facial and auditory nerves to the cranial cavity is much more prone to end in purulent leptomeningitis, involving the internal and external cerebrospinal fluid, and seldom causes brain abscess.

Conclusions.—The question naturally arises, would intracranial interference have availed anything? It was the unanimous opinion of all present at the autopsy that it would not, and the pathological conditions found proved beyond all question that our opinion, formed while watching the progress of the case, was correct, viz., that at no time did the indications warrant trephining. We are aware that a few cases of suppurative meningitis involving the subarachnoid fluid have recovered after operation and drainage. All the cases we found in a hurried search of the literature, which were three in number, followed chronic otitis, while those that followed acute otitis died, autopsy revealing general leptomeningitis. Symptoms of intracranial disease are so varied as not to be an index to the actual conditions present; this is proven by all statistics, where the symptoms were recorded during life and autopsies held to determine those conditions. In those cases that recovered, we can only conjecture as to the extent of the meningitis. The fact that the pus areas were drained and recovery followed undoubtedly proves the meningitis was local. Ballance has well asked the question, "How could the subarachnoid space be drained?" and adds: "The arachnoid spreads from convolution to convolution, and every space between each convolution would have to be opened. When the pus is underneath the visceral arachnoid drainage is impossible."

Macewen has observed that "if the pathological matter enters the subarachnoid space before adhesion with the pia mater has been formed, leptomeningitis is apt to be set up; in which case the whole of the cerebral and cerebellar meninges are apt to be involved, the inflammation spreading with the greatest rapidity along the areolar tissue of the arachnoid. . . . On the other hand, if adhesion between the different layers of the meninges takes place before the infective material reaches the subarachnoid, for a time at least the suppuration will be local."

The symptoms in this case are to be explained by: (1) Increased intracranial pressure. (2) Disturbance of cerebral function. (3) Suppurative leptomeningitis, involving the cerebrospinal fluid.

The consistency of the brain, according to von Bergmann, is such that pressure exerted at any part is transmitted and equally diffused to all parts of the cranial cavity. The effect will be earliest manifested upon the more easily compressed tissues. The walls of the veins have less resistance than those of the arteries and will suffer most. Their points of exit from the skull are bony foramina, which prevent sufficient dilatation to permit the outflow of blood to maintain circulatory equilibrium, resulting in slowing of the circulation and increased congestion. The two conditions reacting, each intensifying the other, cause increased intracranial pressure. So long as the cerebrospinal circulation is maintained, the greater part of the excess of cerebrospinal fluid will be absorbed by the capillaries in the spinal meninges; but as soon as this circulation is obliterated intracranial pressure will be rapidly increased. "If the circulation of the brain becomes gradually slower, the order of the centers affected is as follows: The cortex, corona radiata, gray matter of the spinal cord, region of the pons, and finally the medulla oblongata. . . . Consciousness is more rapidly lost than any other func-

tion, and returns only after the circulation has been fully restored. . . . The persistency of pressure is as dangerous as an exceedingly high degree of pressure" (von Bergmann).

The clinical manifestations of cerebral pressure are divided into two stages: (1) The stage of stimulation. (2) The stage of depression.

We will now attempt to explain the obscure symptoms manifest in our case. The sequence of tissues involved were undoubtedly as given by von Bergmann, cited above.

1. *Pain.*—The pain was due to basilar meningitis. It varied in degree and character until the morning of the 17th, when the infection probably had extended to the cerebral ventricles, and the resulting thick pus obliterated the cerebrospinal circulation. The rapidly increasing pressure caused thereby produced the violent pain, which drove the patient frantic. The morphia quieted him until the increasing pressure became so great as to produce unconsciousness, which continued. The lessened pressure caused by the hemorrhage at the second operation was followed by some improvement in his mentality. We believe the soreness in the mouth was due to irritation of the fifth nerve by the ethmoiditis and basilar meningitis.

2. *Restlessness.*—The pressure produced irritation and, therefore, stimulation of all centers, which stimulation caused restlessness and increased sensory reflexes to the stage of depression, when finally all were abolished.

3. *Temperature.*—High remittent temperature was due to meningitis and absorption of the septic material.

4. *Pulse.*—At first slow from stimulation of the pneumogastric, causing cardiac inhibition: later increased pressure destroyed irritability of this nerve and rapid pulse followed, augmented by the high temperature: the period of slow pulse was unusually short.

5. *Respiration.*—Varied with temperature and cerebral pressure; became Cheyne-Stokes from pressure upon the medulla by the pus in the cerebral ventricles and subarachnoid space.

6. *Absence of Vertigo and Vomiting.*—This was probably due to the gradually increased pressure with no sudden variations in the circulation

7. *Absence of Localizing Symptoms.*—The pressure was exerted equally over all parts of the cortex and therefore produced no localizing symptoms, and was insufficient to cause general convulsions.

TYPHOID FEVER COMPLICATED BY MULTIPLE ABSCESSES OF THE KIDNEYS AND BY LOBAR PNEUMONIA.

By L. NAPOLEON BOSTON, A.M., M.D.,

PHILADELPHIA.

ADJUNCT PROFESSOR OF MEDICINE, MEDICO-CHIRURGICAL COLLEGE; PHYSICIAN TO PHILADELPHIA HOSPITAL; AND DIRECTOR LABORATORIES FOR CLINICAL RESEARCH, AMERICAN HOSPITAL FOR DISEASES OF THE STOMACH.

The physician is ever alert for the development of the renal complications common to typhoid fever. A simple albuminuria (probably febrile in origin) is to be expected during the fastigium in nearly every case of typhoid infection. The amount of albumin excreted through the urine as the result of fever is always small and usually gives a feeble reaction either by heat or by any one of the contact methods.

Acute nephritis may develop at practically any state of typhoid fever, and is placarded by a diminution in the quantity of urine, albuminuria, and the presence of renal casts. With the development of nephritis all the symptoms of typhoid fever are aggravated. Both simple and diphtheritic pyelitis are known to follow typhoid infection.

Judging from the mention made by the different authors of multiple abscesses of the kidneys as a complication of typhoid fever, this must be rather unusual. I have been privileged to study four cases of typhoid fever in which there was anuria lasting for a period of twenty-four hours.

The patient, a clinical and pathological study of whose maladies forms the subject matter for this report, was a German woman, twenty-five years of age, who was admitted to my service at the Philadelphia Hospital, August 26, and died September 10, 1906. At the time of her admission she presented a clinical picture of typhoid fever, and while she was unable to speak English the history obtained pointed rather clearly to the fact that she had been indisposed for about a week.

A physical examination showed the heart and lungs to be normal; the urine was practically normal, and the temperature was 101.4° Fahr. The symptoms of typhoid fever grew worse, and three days after her admission there was pronounced tympany, marked intestinal pain, especially with each movement of the bowel, and extreme tenderness in the right iliac fossa and along the ascending colon. At this time there was a rather liberal eruption over the abdomen and chest.

During the third day of her stay in the hospital she was seen to be somewhat cyanosed, respirations were hurried, the pulse increased from 106 to 120 per minute, and numerous râles were audible at the base of the right lung. The urine contained a trace of albumin.

The fourth day (approximately the twelfth day of the fever) delirium became maniacal, and it was found necessary to administer a portion of the medication hypodermically every four hours during the following day. Each hypodermic contained digitalin gr. 1-100, strychnine sulphate gr. 1-48, and nitroglycerin gr. 1-120. Three or four times daily she was given an enema of milk, to which had been added a liberal quantity of milk of asafetida, with a view to reducing the abdominal distention, which was perceptibly lessened after each enema. Stimulants and codeine sulphate were given by mouth whenever possible.

The lung condition progressed from bad to worse until there was consolidation of the lower half of the left lung. Singularly during the fifth day in the hospital (twelfth or thirteenth day of fever) the patient did not void any urine, nor was there any urine found in the bladder upon catheterization. The temperature ranged near 103° Fahr. and was of the continued type.

Early the following day she voided three ounces of dark urine which was rich in albumin. Throughout the day cyanosis increased and the pulse became weak, thready, rapid, and irregular. The delirium ameliorated some, but there was still evidence of a migratory pneumonia which was spreading, and anuria obtained most of the day.

In consequence of the temperature having risen to 104° Fahr. the patient was given a cold sponge bath, to which she reacted very unfavorably, becoming pulseless, with cold extremities, temperature 99° Fahr. (by vagina), and marked cyanosis.

The bath, while it was borne badly, may have exercised some influence upon the action of the kidneys, since the following day the patient voided 49 ounces of urine. The patient's general condition

was much improved twelve hours after the cold sponge bath, and the kidneys were functionating actively.

The urine was highly acid, specific gravity 1.014, gave a decided reaction for albumin, and the diazo-reaction was present. Microscopically there were found many short and long hyaline renal casts, many both broad and narrow granular casts, numerous leucocytes, and a few red blood-cells. Epithelial cells were present in great numbers, but they were never found intimately connected with renal casts, consequently it was impossible to say beyond question of a doubt that they were renal in origin.

Surrounding the site of puncture of each hypodermic there was a small hemorrhage in the skin, and these hemorrhages varied in size according to the time since the hypodermic had been given. Ecchymoses from hypodermics given during the previous night did not exceed one-eighth of an inch in diameter, while those which corresponded with the hypodermics given forty-eight hours earlier varied from one-half to one and one-half inches. The cause of these cutaneous hemorrhages was not satisfactorily explained, since they continued to form even when digitalin and nitroglycerin were not administered with the hypodermics. The cutaneous hemorrhages must, therefore, have depended for their production upon the local irritation excited by the puncture of the hypodermic needle, and further upon a predisposition of the patient toward the development of cutaneous ecchymoses.

Two days later, and for a second time, the patient displayed the symptoms of uremia, in addition to those already present resulting from the double croupous pneumonia and typhoid fever. The respirations, which were 45 per minute, were reduced to 38, and the pulse of 140 and of low tension became stronger and of better volume at 120 beats per minute. Increased arterial tension and lessened frequency in the respirations may be a precursor of grave renal complications in acute fevers. Again, for a period of twenty-four hours the patient did not void any urine, and during this apparent recurrence of renal involvement she entered into a semicomatose state, which was soon followed by general collapse.

The post mortem made upon the body of this patient was conducted by Dr. Joseph MacFarland, Pathologist to the Philadelphia Hospital, who gave a pathological diagnosis of "Typhoid fever, pulmonary infiltration with atelectasis, parenchymatous nephritis with infectious emboli of the kidneys, parenchymatous degeneration of the liver, and acute splenic enlargement." I have abstracted from the pathological records such points as have special bearing upon the general symptomatology of the case under discussion.

The pericardium and leaflets of the heart were normal, although the cardiac muscle showed some evidence of degeneration, but nothing more than is to be expected in severe febrile conditions.

The left lung weighed 360 gm. The superior lobe and one-half of the inferior were involved by an acute pneumonic process, while the remaining portion of the lung was collapsed. Excised fragments from the consolidated portions of the lung sank immediately when placed in water.

The right lung weighed 440 gm., displayed a few pleural adhesions at the base, and the inferior lobe was completely involved by an acute pneumonic process which was apparently identical with that displayed by its fellow.

The spleen weighed 280 gm. and measured 11x14x3½ cm. Its edges were blunt and decidedly thickened, the organ was soft, and upon section the cut surface was purplish red and fairly characteristic of that found in typhoid fever.

The condition of the kidneys was equally striking in interest with that presented by the lungs. The left kidney weighed 230 gm., was slightly enlarged, and presented a smooth slate-colored surface. Upon section the organ cut easily and its capsule stripped readily, leaving behind a highly congested surface. Both upon the cut surface and underneath the capsule there were seen a number of small septic infarctions, which appeared to be rather evenly disseminated throughout the greater portion of the cortical (medullary) substance of the kidney. At one point there was a swelling about 1 cm. in diameter, due to an aggregation of minute abscesses. The cut surface of the kidney was decidedly grayish in color and displayed extreme congestion at the base of the pyramids. The pyramids also showed some striation as the result of septic emboli.

The right kidney weighed 240 gm. and generally speaking the lesions presented by it were identical with those found in its fellow.

The liver weighed 1,690 gm. and its surface was decidedly nutmeg in appearance; the organ was somewhat softened as a result of congestion.

The colon, from the ascending portion onward, displayed only a moderate degree of congestion. The ascending colon presented a few ulcers, which were about 1 cm. in diameter. At the cecum there was a marked aggregation of small ulcers, which covered more than one-half of the mucous surface, and there was also extensive ulceration at the ileocecal valve. The first 10 cm. of the ileum was almost entirely occupied by an extensive ragged ulceration resembling that found in the cecum, and beyond this point there were many deep, ragged ulcers, corresponding to the situation of Peyer's patches. A few of the ulcers were situated transversely to the intestine (a feature characteristic of tuberculosis and not of typhoid fever), but I am inclined to regard this peculiar arrangement of the ulceration as dependent upon extensiveness of the process and not due to tuberculosis.

1531 South Broad Street

THE PREVENTION OF DISEASE.*

By EDWARD E. FEILD, M.D.,

NORFOLK, VA.

SURGEON TO ST. VINCENT'S HOSPITAL.

In order to discuss intelligently the prevention of disease it is necessary to classify all diseases with reference to their causation. For the purpose of this paper, all disease is due either to some inherent degenerative change or error of metabolism, or to some extraneous cause introduced into the system. To the latter class belong the infectious and contagious diseases, so called. As these terms are often loosely applied, I shall adopt the suggestion of Rosenau and speak of them as "communicable" diseases. In this paper I shall assume that the discussion of communicable diseases only is intended, as they are from a sanitary standpoint the only preventable ones. The communicable diseases I shall divide for convenience into two classes:

1. Those diseases caused by animal parasites.
2. Those caused by bacteria.

The animal parasites are divided into three subclasses:

*Read at the "Symposium on Preventive Medicine" of the Virginia State Medical Society at its annual meeting at the University of Virginia, October 9 to 11, 1906.

A. The various parasitic insects, as fleas, bedbugs, pediculi, ticks, etc.

B. The helminths, as lumbricoides, ascarides, teniæ, ankylostoma, etc.

C. Protozoa, which require for their development and transmission a separate cycle of existence in an intermediary host, as the hæmatozoa of malaria, yellow fever, rabies, filariasis, and some of the trypanosome diseases, and probably smallpox and relapsing fever.

It is obvious that in diseases of such dissimilar origin many of the measures adopted for the prevention of one class will be totally useless in the other.

It is not within the scope of this paper to enter further into the etiology of these diseases. As far as possible it will be attempted to deal with a class rather than with a single disease.

Among the protozoan diseases yellow fever occupies a prominent part, being the disease most dreaded in our Southland. It has been demonstrated to the satisfaction of the large majority of nosologists that the only method of convection of yellow fever is through the medium of the *Stegomyia fasciata*. Of course, then, our efforts should be directed first towards preventing infection of mosquitos, and secondly towards their destruction. The first is accomplished by screening all patients sick with yellow fever for the first three days of the disease (after which time they become noninfective to mosquitos), screening of all doors and windows to prevent ingress and egress of all mosquitos which might have become infected, and destroying them after removal of the patient. The material which seems most efficacious in their destruction is "culicide," a preparation consisting of equal parts of camphor gum and crystalized carbolic acid (by weight) rubbed together, forming a liquid which is colored with methylene blue, eight grains to the gallon, and volatilized by heat.

After a room has been exposed to the fumes of culicide (4 fluid ounces to 1,000 cubic feet), the mosquitos fall to the floor and are swept up and burned. Culicide was mainly used in the epidemic of yellow fever in Louisiana last winter, and I am informed by one of the officers of the Public Health and Marine Hospital Service, who had charge of the disinfection of houses, etc., that it was very efficient in destroying the various forms of animal life, but was in no way harmful to even the most delicate fabrics. Of course, the propagation of the mosquito should be prevented as far as possible by screening cisterns and rain barrels, filling all holes, and destroying all broken bottles or other empty receptacles in which stagnant water might be found, and oiling those pools of water which cannot be filled, in order that the larvæ may be destroyed. Upon the appearance of yellow fever in a community, that community should be quarantined at once by Federal authority, camps established, and if, after five days' detention of persons desiring to leave, no symptoms appear, such persons should be allowed to travel anywhere without restriction. Their baggage and the cars in which they travel should be fumigated in order to destroy all stegomyiæ present. The method used in yellow fever for destroying mosquitos should be used in malarial cases also, as the two diseases have many points of resemblance with regard to causation and symptomatology, and I believe the time is not far distant when the yellow fever germ will be discovered and shown to have characteristics similar to those of the hæmamœba malariæ. The *Stegomyia fasciata* is a domestic mosquito and does not fly far away from its birthplace, consequently, by destroying their breeding places around dwellings, we practically eliminate the danger of a spread of yellow fever.

Authorities differ as to the domesticity of the *Anopheles*. Howard says: "They have always been found in more or less permanent pools of water, either in the bed of an old canal, or in spring-fed woodland streams, or in the side pools or shallows of field springs, or in artificial excavations filled with surface water. They are rarely found in water in barrels or troughs, and rarely found in the same water with larvæ of *Culex*." This would seem to show that they are to a great extent wind borne, especially as malaria usually seems worse on the north side of a stream, the prevailing winds in summer and fall being southerly.

I am not aware that any experiments have been made with regard to the period during which a malarious person is infective to mosquitos, although that would seem to offer a fruitful and interesting field for scientific research.

The efficacy of the method adopted for preventing malaria in the Campagna by administering quinine and screening patients has been fully demonstrated, and has accomplished more for that purpose than all the previous draining of the marshes. The same method used by the German government in Africa has been productive of similar beneficial results. It would then seem to be an easy matter to rid our country of malaria by carefully screening patients and others, rendering them noninfective to the anopheles, and destroying the mosquito.

Rosenau has shown that of the chemicals used for fumigation sulphur fumes are most destructive to the various forms of animal life, while formaldehyde is the better disinfectant for bacteria. Since that time culicide seems to destroy small animal organism even better than sulphur. According to Councilman, Guarnieri and others, smallpox is caused by a protozoon, as is also rabies. It is unnecessary to suggest to this intelligent body that smallpox can be easily stamped out by vaccination and isolation; there are few diseases which can be so satisfactorily and easily prevented. The limits of this paper prevent the discussion of the diseases caused by the other animal parasites. I will, however, suggest that ankylostoma seems to be threatening the South Atlantic and Gulf States, as shown especially by the intelligent investigations of Charles Wardell Stiles.

The Various Bacterial Diseases.—It will be necessary to class under this head many diseases whose specific germs have not yet been isolated, but whose symptomatology and course resemble so closely bacterial diseases as to prevent their being classified elsewhere; *e.g.* measles, and diseases caused by spirochætæ.

Methods of Convection.—(1) Mediate or immediate personal contact with patient. (2) Through invected environment (fomites). (3) Food or water supply. (4) Through medium of rats and domestic animals, flies and other insects. (5) Through desiccated or partially desiccated bacteria in dust, taken into the system through the respiratory or digestive tract. (6) Through abrasion in the skin, as in pyogenic diseases, diphtheria, syphilis, ankylostoma, etc.

Our possessions in the Philippines, West Indies, and Panama, and our increasing commercial relations with South America and the Orient, constitute a menace to our country in the importation of tropical diseases. Not only may the disease-carrying animal and various bacteria be kept alive during

the continually shortening voyages, but many persons resident in the tropics may bring within their systems the various trypanosomes and other organisms and infect the fauna of this country. The best method to prevent the ingress of these diseases is to inspect all such travelers at the point of departure, and also upon their arrival at quarantine. A strict, intelligent quarantine will keep out most of the so-called quarantinable diseases—cholera, typhus fever, smallpox, leprosy, plague, and yellow fever. Of these the one to be most dreaded is plague, on account of its greater insidiousness, greater difficulty of extermination, and higher rate of mortality.

According to Kitasato the pest bacillus is carried by raw cotton or grain. The infected grain is eaten by rats, which thus contract the disease. The sick and dead rats are eaten by others, so that in a short time the entire rat colony is infected. Thus the bacilli are disseminated and enter the system through abrasions of the skin or by the respiratory passages or alimentary canal, or through the bites of fleas.

Kitasato advises the thorough disinfection and fumigation of premises, destruction and cremation of rats, building of rat-proof houses, and cremation of all persons dead of the disease.

It is assumed that the usual course of fumigation and disinfection during and after the course of the communicable diseases is so well understood by the average practitioner that reference will not be made to it further than to mention under certain diseases some special measure peculiar to the convection and prevention of each.

And here I would state that for the purpose of fumigation formaldehyde is more destructive to bacteria than culicide or sulphur dioxide, while the reverse is true in the case of animal parasites of all kinds. In the fumigation of houses, ships, and railroad cars, paper should be pasted over all cracks around windows and doors to prevent the escape of the fumes, and the room kept closed for twenty-four hours, in order that all bacteria may be destroyed. The methods of generating the fumes of formaldehyde adopted by the Illinois and other State boards of health is so simple and practical that I shall insert it here. It requires no heat, but a somewhat larger percentage of potassium permanganate should be used (about 8 ounces to get the best results). The method is very simple, requiring no apparatus except a tin pail of sufficient capacity, best made with flaring top. It is made with a double bottom with one-quarter inch air space between the layers of tin, and is entirely covered on the outside with asbestos paper. Instead of this apparatus an ordinary milk pail set into a pulp or wooden bucket will answer every purpose.

The room is sealed, fine needle-shaped crystals of potassium permanganate (3½ ounces to each 1,000 cubic feet of air space) are placed in the container. Over this salt is poured 40 per cent. solution of formaldehyde (1 pint for every 1,000 cubic feet of air space). The operator should leave the room quickly, as large quantities of gas are at once evolved. The results of laboratory experiments have shown that the gas thus evolved acts more thoroughly on account of its great concentration, and kills very resistant microorganisms, even when concealed under several thicknesses of cloth. The Maine Board of Health recommends 6½ ounces of permanganate and two pints of formaldehyde solutions for every 1,000 cubic feet. Presence of moisture in the air is essential. The disinfection of the room, the woodwork, furniture, and floors with liquid disinfectants (mercury bichloride, 1 to 1,000) is as important in this mode of disinfection as in any other. The method requires the use of common and relatively cheap chemicals, so that it is estimated that the disinfection of 1,000 cubic feet costs about 75 cents. Based on this method, proprietary preparations are on the market under fanciful names, and for which extravagant claims are made, but they are in no way superior to the simple methods, and their use should be avoided because of the uncertainty as to the amount of gas they will evolve.

Next in importance is cholera, but owing to its severe and easily recognized symptoms, and the much feebler vitality of the spirillum, its prevention is accomplished with less difficulty. Cholera is acquired through drinking water. However, the spirillum is kept alive upon fruits and other edibles. The usual precaution of isolating the patient should be taken as far as possible. This is usually easily done in the more acute communicable diseases, as smallpox, diphtheria, cholera, etc., but it is not practicable in the venereal diseases. Pneumonia and typhoid fever should by all means be isolated. Physicians and others who come into enforced contact with such cases should disinfect themselves thoroughly before mingling with other persons. The patient infects his surroundings through the feces and urine, expectoration, vomitus, breaking down of abscesses, as in streptococcus infection and bubonic form of plague, and probably in all of the exanthemata by desquamation. These bacteria are of varying degrees of vitality, the spore-bearing bacilli, such as tetanus and anthrax, being the most hardy, and often retaining their vitality on clothing and other fabrics, in dust and in water or food. Even so delicate a germ as the cholera spirillum is not killed by considerable exposure. The proper disinfection of cups and other utensils used by patients, the destruction of all food left by them, the disinfection of all excreta before leaving the sick room, should be strictly insisted upon. Carbolic acid or trikresol, rather than bichloride, should be used for disinfection of stools, urine, or sputum.

Dr. Doty's method of disinfection of stools, as quoted by Dr. Grandy in the *Virginia Bulletin of Health*, seems to be an admirable one. He makes the following solution: Copper sulphate, 1 pound; lime (unslaked), 1 pound; water, 10 gallons. Put the copper sulphate in cotton bag and hang it in 6 gallons of water. Pour the rest of the water on the lime, and mix the two solutions. Stir well before using. This solution should be kept on hand, and should be poured over and thoroughly mixed with the typhoid urine and stools, which should stand in it for at least half an hour. It is not only a good disinfectant, but a deodorant, and might well be generally used in country privies, from which germs can easily be carried to the kitchens by flies. This is a source of typhoid infection which is often overlooked, but which was responsible for typhoid epidemics among our soldiers during the Spanish War, and which is probably often the cause of cases which appear in the house with a convalescent typhoid fever patient, whose urine and stools are not disinfected. While this applies especially to the rural districts, typhoid urine and stools should also be disinfected before being emptied into the city sewers, as these often flow into rivers from which other towns draw their water, or into bays from which oysters are taken.

In all the respiratory diseases the sputum should be received on cloths and immediately destroyed by burning. Sweeping should be avoided as far as possible in a sick room, and all dust removed with

a damp cloth. Many germs are doubtless expelled through the "insensible expectoration" during coughing in tuberculosis, influenza, and the pneumonias, and probably also in typhoid fever. Since the latter disease is known to be a septicemia, with a probable first infection in the lung in many instances, it is fair to presume that its bacillus does undergo a desiccation or partial desiccation, and it is to that extent a wind-borne disease. The *Bacillus typhosus*, according to Park, has been kept alive sixty-four days in dust. In cities dust should be prevented as far as possible by sprinkling the streets and sweeping and removing the dust before it dries. It should be remembered that the typhoid bacillus remains in the urine and feces of a patient for weeks after recovery.

Droppings from horses should be removed from the streets at once, as they are a breeding medium for flies. Flies breed usually in and around stables, preferably in the dung of the horse, and also in garbage. It is therefore necessary that garbage be collected and destroyed as rapidly as possible. Flies carry infection by lighting upon a patient or the infected excreta and afterwards falling into water or food and infecting it. There is evidence that some flies play the part of an intermediary host and convey the disease by biting the patient, as in the case of the Tsetse fly, which carries the trypanosome of sleeping sickness. Flies should be excluded from houses as far as possible by screens, and killed by fumigation with culicide or sulphur. Fleas, bedbugs, etc., act as carriers of infection, and should be exterminated.

Milk being an excellent culture medium for many of the pathogenic bacteria, is a fruitful source of infection in a number of the communicable diseases. Rosenau says (Disinfection and Disinfectants, page 214): "Of all foods, milk is most likely to be infected. It is a very good culture medium for almost all the pathogenic bacteria; for instance, fresh milk contaminated with a few typhoid, diphtheria, cholera, or plague bacilli, will in a few hours at ordinary temperatures have every drop teeming with many of these organisms without appreciably altering the appearance of the milk. It is easy to understand how readily the infection of typhoid fever, cholera, diphtheria, or plague may get into the milk. The exanthematous diseases have frequently been traced to the milk supply. The possibility of tuberculosis being conveyed in the milk is ever present. The milk supply in a large city is always under suspicion, so frequently does it carry disease." The source of the milk supply should be thoroughly examined. Every case of sickness among the attendants of dairies and their families should be carefully investigated. Cows should be examined for tuberculosis and other sickness, and all ailing ones killed, or sent away. They should be well fed, well bedded, kept thoroughly clean, and given plenty of good clean water. No water closets should be allowed near the dairy nor its water supply. Milking should be done, after thorough cleansing of the udder, in a clean separate milking room, into covered buckets, or the milk should be strained through sterilized cloth. The milk should be placed where it cannot be contaminated by dust, and marketed in bottles sterilized by steam and never refilled from the wagon.

Epidemics.—In the case of epidemics it is necessary to prevent public gatherings. In the smallpox epidemic in Norfolk, in 1899, it was found that after a severe cold spell the number of cases of the disease among the negroes was always increased. This was attributed to their huddling together in barrooms and other such resorts for warmth.

The schools, public and private, should be carefully watched for communicable diseases, and no pupil residing in a house where such diseases exist should be allowed to attend, nor should any person not vaccinated be admitted. In all schools pupils should be taught at least the elementary rules of sanitation and hygiene. They should be instructed in the danger of expectorating on floors, of swapping chewing gum, and of other sociable but pernicious practices. Individual drinking cups should be used. The same rules should apply to factories, department stores, and other places where people most do congregate. Such places should be supplied with fresh air and sunlight as far as possible.

In conclusion I desire to say that in epidemics of cholera, plague, or yellow fever, the federal government should take charge of all cases and be given full power to stamp out the disease and regulate travel. Witness the good work done in the yellow fever epidemic in New Orleans last year, with no return. How much delay and interference with traffic could have been avoided but for the concealment of the disease in the first intance, and the consequent illogical and useless gunshot quarantine. Quarantine should mean the maximum protection to health with the minimum interference with business.

THE HAND OF IRON IN THE GLOVE OF RUBBER.*

By ROBERT T. MORRIS, M.D.,

NEW YORK

In the Middle Ages there was an ogre on the other side of every hill.

People gradually overcame their fear of ogres, and began to get scared about witches.

After witches had been duly burned, surgeons were frightened about opening the peritoneal cavity. When I was a student, we were taught to have a chill whenever the subject was broached, and the textbooks described various ways for avoiding the grewsome mishap.

After ogres, witches, and normal peritoneum had been disposed of, we began to enjoy a fear of pus in the peritoneal cavity. Surgeons passed through the transition period of washing their hands after operation instead of before, and arrived at the stage of aseptic preparation of the hands. Then, in logical sequence, we began to wear rubber gloves, and employed them in intraperitoneal work, even though infection were already present. What do you think of that?

Charlemagne baptized a lot of Mohammedans and then laughed up his sleeve when he saw them gravely bowing to the East after that, for he knew that they were securely Christians. We put on rubber gloves and smiled at the thought of bacteria doing a thing to the patient after we had conscientiously tried to remove infection which could in fact be removed best by the patient himself. Worse than that, when we put on gloves for a boxing match with the patient's vitality, we rapidly placed him in an unfavorable position for self-defense. The use of rubber gloves made it necessary to use such long incisions that we could work by sight, and this lowered the patient's vitality.

Long incisions are employed for killing bears, and we chose for saving weak patients the methods which are in use for killing bears.

Rubber gloves led to slow work, and that further

* A paper read before the meeting of the Surgical Section of the New York Academy of Medicine, February 1, 1907.

reduced the natural resistance of patients. Tait without antiseptics or asepsis showed that his facile fingers could bring out better statistics than we can get with an iron-like hand in a glove of rubber. Tait was a thorn in the side for most of us. Nowadays we understand that he conserved the natural resistance of his patients, and turned the management of infections over to them, but in his day the only comfort that we could get was in the forlorn hope that he might be untruthful. Tait was a perennial insult to us, unless we could get even by making a retort.

Slow work means a longer period of anesthesia—a longer debauch with an intoxicant.

Have we not reached the stage of information where we can drop our fears of ogres, witches, normal peritoneums, and pus in the peritoneal cavity?

Do we not know that much of this pus is sterile, in spite of its odoriferous mercaptans and sulphur ethers, and that bacteria are chiefly at work in the tissues rather than in the pus? Is it not time for us to realize that we cannot get bacteria out of the tissues, but that the patient is finely equipped for attending to the work if we do not disable him ourselves?

Simple, quick work which merely turns the tide of battle between bacterium and phagocyte is what the patient needs when he calls us to his aid, and simple, quick work is not facilitated by the use of rubber gloves.

The patient with an infection under way is a factory. His chief business is the manufacture of opsonins for wounding bacteria, and phagocytes for disposing of them afterward. The hand of iron in the glove of rubber throws the belts from the wheels in this factory.

We must not forget that even in such a disease as appendicitis, with pus in the peritoneal cavity, very many patients recover without operation. How do they manage it? We know. We must not forget that we know how it is done, when we step in to improve upon nature's methods.

Let us not commit taxidermy upon valued citizens by stuffing them with gauze, or lower their natural physiological resistance with the kindly helpful hand reduced to second grade by a glove.

After the period of infection has passed, can we separate peritoneal adhesions in the best way by putting on a handicap, and allow the patient to escape with a mild attack of surgery? Not according to my observations.

There are places in which rubber gloves should be used. In opening an uninfected knee joint, for instance. The house staff at the hospital would transfer too many proliferating colonies of bacteria, if rubber gloves were not worn on rounds when dressings are changed.

In some outside work, as in hernia operations, where we work by sight anyway, rubber gloves will give the best statistics, unless the slower work allows more bacteria to fall in from the air than would be carried in by the hands. That last point is an important one. Among human faculties the sense of proportion ranks just above moral sense in value. Psychologists may not agree with me, but they do not agree with each other. It is discrimination that we need more than rubber gloves. The subject allows of pretty good classification in a general way.

Rubber gloves may be useful: (1) In cases in which there is no infection or other disease to call out the patient's natural resistance to infection. (2) Where dressings are to be changed for several patients in succession, or where the surgeon operates upon an uninfected patient shortly after operation upon an infected one. In the latter case, if the patient were to be consulted in the matter, he would probably ask to have his operation deferred until spring anyway. Rubber gloves are not needed—or worse than that: (1) Where infection is already under way, and the patient is calling out his own protection. (2) Where a disease like cancer has already called out such a degree of protection that the old-time war doctors could amputate a breast and get primary union under "well-waxed shoemaker's thread" that had been held in the mouth or over the ear while operation was in progress. (3) Where no infection or other disease is present, but where slow or extensive operating necessitated by ungainly gloves will allow more bacteria to fall into the wound than would be carried in by well-prepared bare hands.

The argument has been made that the surgeon should wear rubber gloves for his own protection. For whom are we working?

The coming generation of surgeons, brought up on rubber gloves, will not do the wizard-like work that was done by some of the older operators, excepting in instances where discrimination has been the rule, and where the fingers have been taught better tricks than the eye ever knew.

Our surgery is not different from vegetable surgery. For recreation I hybridize hickories. It became necessary to find an expert grafter. High and low, all over the country search was made. Horticulturists all said the same thing. "Hickories cannot be grafted. Millions of dollars a year would come to us if we could do that grafting." Finally I found a man in Massachusetts who could catch 25 per cent. of hickory grafts, and a man in Texas who could catch 90 per cent. of them. Both said that there was no trick about it at all. Nothing was needed but quick, neat work. Surgeons have to face precisely the same situation. A few will do with ease what most others say cannot be done at all. Rubber gloves will debar surgeons from doing some of the most expert work that lies within the range of their capabilities.

I have no confidence in any man who does not believe that his own country excels in everything, no matter where he lives. From that standpoint of patriotism I want to believe that America has the best surgeons in the whole wide world, and that we are to be the first to drop rubber gloves whenever pathology and mechanics teach that handicaps are not desirable.

Rubber gloves are pretty, but let us not put on these badges of inferiority for every entertainment. Let us not join with wars and epidemics in doing honor to the shade of Malthus.

616 Madison Avenue.

Arteriosclerosis.—Devoto says that in arteriosclerosis there is not an exact correspondence between the anatomical alterations and the clinical phenomena. He enumerates the causes that may produce the condition, and states that in defining the relation between arterial pressure and arteriosclerosis we should not omit those causes which favor the chronic renal lesions, hypertrophy of the thyroid, alterations of the respiratory organs, and those which result from insufficient food. From the point of view of therapeutic treatment, he says that the symptoms which show the existence of arteriosclerosis, such as modifications of pressure, etc., can be favorably affected by iodine and other chemical and physical means.—*La Riforma Medica.*

INTRAABDOMINAL ABSCESS DUE TO GONORRHEAL AND BACTERIUM COLI INFECTION COMPLICATING PREGNANCY; OPERATION WITH COMBINED VAGINAL AND ABDOMINAL DRAINAGE; RECOVERY.*

By S. STRAUS, M.D.,

NEW YORK.

GYNECOLOGIST TO THE PHILANTHROPIC HOSPITAL; LECTURER ON GYNECOLOGY, NEW YORK POLYCLINIC MEDICAL SCHOOL AND HOSPITAL.

Mrs. L. M., housewife, aged 18, married 6 months, was never pregnant before. Menstruation began at 12 years of age, regular every 28 days, lasting from 3 to 4 days, with slight pain. Last menstruation September 4. On December 4 there was a profuse hemorrhage, which the patient claimed was menstruation, lasting 10 days, accompanied with headache, loss of appetite, and sleeplessness. The patient always enjoyed good health until her marriage, which was in June. Four months later she became pregnant; she then complained of painful urination, burning discharge from the vagina, and abdominal tenderness accompanied with vomiting.

I was called in to see her after she had been lying in bed four weeks suffering with acute abdominal pain and occasional attacks of vomiting and constipation which had been treated with ice-bags and injections of morphine without avail; she now complained merely of anorexia and extreme weakness; no pain; temperature, 99°, pulse, 86.

The patient appeared anemic and had the general appearance of sepsis, although temperature and pulse were not elevated. External palpation revealed a mass which was felt about two inches above the umbilicus, extending downward into the pelvis, the lower border not being definable by external palpation.

Internal examination. Urethra normal, vagina soft and velvety to the touch, cervix and anterior vaginal wall very soft, uterus enlarged and anteflexed, about two finger breadths above the symphysis and markedly fixed. In the left hypochondriac region a mass was felt filling out the pelvic brim and connected with the uterus and drawing same upward. The diagnosis of a three months' uterine gestation, complicated by diffuse suppuration, was made: the cause of the suppuration we presumed to be left adnexal disease or that infection of an extrauterine sac had taken place. An immediate operation was advised, and the patient was taken to a private hospital and prepared for a vaginal and abdominal section.

On account of the height of the mass from the vaginal fornix there was a doubt whether we could reach the same by vaginal section, still an incision was made in Douglas' pouch with the expectation of reaching the mass this way, aided by external pressure. There were a great many intestinal adhesions, and in one spot the aspirator was thrust in but no pus was found. At this time the patient's condition became alarming, the pulse going up to 150. As I did not wish to prolong the operation, a hasty abdominal section was performed: on entering the peritoneal cavity the omentum, intestines, and uterus were found to be matted together and adherent to a sac containing a large amount of fluid. No line of cleavage could be found. In order to hasten the operation, on account of the precarious condition of the patient, the adhesions were not disturbed, gauze pads being inserted to shut off the general peritoneal cavity. The omentum was bluntly perforated, being torn through with the fingers, the sac was incised, and the pus mopped out with gauze sponges. On investigation the sac was found to be adherent to the intestines, there undoubtedly having been a rupture of a pus tube. It was then decided it would be impossible to extirpate the diseased sac *in toto*, therefore drainage was established through the pouch of Douglas, a large iodoform wick being introduced through the abdominal incision and brought down through the vagina. By this time the patient's condition was wretched, pulse 200, and she was in profound collapse; a transfusion of 1,500 c.c. saline solution was given in the left cephalic vein while the patient was on the table and she was hurried to bed, with the conclusion of all that she would not live longer than half an hour. The patient rallied, however, and about midnight appeared to be coming out of shock. Fearing intestinal obstruction, we attempted to establish catharsis, but large doses of calomel and salines were ineffectual; the abdomen began to swell and symptoms of intestinal obstruction, vomiting, and tympanites began to manifest themselves; large doses of eserine also were given without avail. Under aseptic precautions the gauze was loosened and a digital exploration was made which revealed a kink in the intestines; this was released by the finger, and so great was the rush of fluid through the gut that it was feared that it had ruptured; the tympanites slowly disappeared, and within an hour the patient passed gas and during the night had an evacuation; from this time she began to improve; the gauze in the abdominal wound was changed on the fifth day.

On the third day she began to have uterine contractions accompanied by much pain in the abdomen and during the night she was delivered of a three-months' fetus, but the placenta did not come away; the fetus was removed and the cord was ligated, returned into the vagina, and allowed to remain in order that it might separate of itself, this course being pursued on account of the extreme weakness of the patient; also I did not desire to disturb the relations of the parts unless compelled to by some urgent indication. On the fifth day the patient had a hemorrhage from the uterus which necessitated the removal of the placenta; this was a very difficult task to perform, as it was impossible to make bimanual pressure upon the uterus. The only method that could be employed was fixation of the uterus with a vulsellum forceps and extraction of the placenta with forceps, taking it away piecemeal, followed by curettage and packing of the uterus to prevent any further loss of blood. The subsequent course of the case is explained by the temperature chart: the pulse remained at the level of 120, temperature 102°, and the patient gave promise of approaching convalescence, which was somewhat retarded by the abdominal Mikulicz dressing, which was changed from time to time; the gauze in the cul-de-sac was slowly removed and a new pack introduced, which was changed every five days; the bacteriological examination of pus showed gonococcus and the colon bacillus.

The case is unique in that it lacked the usual constitutional symptoms of any pus formation, and the apparent local signs were only those of uterine gestation complicated by the gastrointestinal symptoms of pregnancy. In the technique employed attention is called to the fact that it is wiser not to separate the adhesions over a large area when we fear pus, but to proceed cautiously with a blunt dissection through the omentum until the sac is reached, emptying same, and then establishing the relations to the adjacent structure.

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

THOMAS L. STEDMAN, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51 FIFTH AVENUE.

New York, March 9, 1907.

THE PRESENT STATUS OF OPSONINS.

FEW of the medical journals of recent issue have appeared without containing either an original contribution upon, or a reference to the opsonic work of Wright and Douglas. Most of these are reports of favorable results obtained in treatment by the methods of Wright, and, as such, are bound to influence the practitioner, breeding in the minds of those who are too busy with the toil of daily routine to follow the details of scientific research an impression that the panacea for all infectious ills has been revealed, and the road opened toward a revolution of the science of immunization.

It is natural and altogether beneficial that every new scientific announcement should be followed, at first, by an enthusiasm which, in therapeutic application and prophecy, may far outstrip the final actual gain. Thorough scientific comprehension follows more slowly, and there is much statistical material gathered by the enthusiastic therapeutists who by their successes and failures, honestly observed, aid much in the final calculation of the net profit. The problems involved in the application of Wright's principles to treatment have not reached the stage at which this final calculation can be made; but it is well at the present time to consider to what extent Wright's important discovery has become the legitimate property of the clinician, and how much of it is still in that stage of uncertainty during which only patient and conscientious research of trained laboratory workers can hope to decide finally upon its actual therapeutic value.

The problems of phagocytosis have long been the subject of much laborious investigation by the French bacteriologists, notably Metchnikoff. The action of the blood serum in the process of phagocytosis has been conceived by Metchnikoff and his pupils, by Bordet, Denys, Mesnil, Besredon, and others, as rather a stimulation of the phagocytic cell than as an influence exerted upon the ingested bacteria or other substances. The knowledge brought out by the studies of Wright and Douglas, and those carried on independently, though somewhat later, by Neufeld and Rimpau, show us that this phagocytic power bestowed by the serum is set in motion by an action upon the ingested objects rather than by the changes wrought upon the leucocytes themselves. That the substance which brings about this loss of resistance to phagocytosis—the "opsonin"—is probably independent of agglutinin, complement, and the various other substances present in normal and immune sera previously described, must, in the light of our present knowledge, as based on the work of Hektoen and others, be assumed. Thus a far-reaching new truth has entered into our knowledge of the phagocytic process, a truth the recognition of which in itself is a great achievement, and which, by its own weight and indirectly by the great stimulus it has given to research into the phagocytic elements of immunization, may lead to still greater results.

As to the present therapeutic application of this new principle, so much is being said by enthusiastic workers that it is hardly necessary to outline what is going on. Active immunization with minute dosage of dead organisms is the principle of Wright's work. Active artificial immunization in itself is an old matter, and is obviously limited to subacute and chronic processes. The mistakes of earlier workers in this field undoubtedly to a large extent lay in overdosage and ill-judged intervals, and others, without knowledge of opsonins, have been working toward the correction of these errors. This has been the tendency in many sanatoria for tuberculosis, both here and in Europe, and the book of Denys, published in Louvain in 1904, is based upon this principle of active immunization by small dosage of his bouillon filtré of cultures of the tubercle bacillus. But all these observers have relied upon purely clinical data in their judgment of the reaction to the treatment and for standards of dosage and time of repetition. Wright and his disciples, on the other hand, are basing their judgment in these matters upon the rises and falls of the opsonic indices of the patient's serum.

It undoubtedly would seem at first sight that such actually visible changes in the specific phagocytic power of a patient would be more delicate than the rough data of clinical observation of temperature, physical signs, and general condition, and even the sceptic will acknowledge that the determination of the opsonic index in a given case may, together with clinical data, be of value. But to obtain this systematically entails much time, work, and expense, and it is but fair to inquire whether this addition to the labor of treatment will justify itself by shedding a corresponding amount of light upon the condition of the patient's resistance. This question resolves itself into an examination of the accuracy of opsonic estimations.

The details of a technique which is both intricate and delicate cannot be gone into here; suffice it to say that the mere mechanical labor is a matter requiring much skill, in which minute variations of eye and hand may lead to considerable errors in the result. The opsonic index is calculated by a comparison with an arbitrarily designated "normal," and these "normals" so-called are subject to great variations which, as the numerators or denominators of the final fraction, thus add another and purely arbitrary error to the result. The leucocytes used for these estimations are taken from an indifferent source, usually the finger of the worker himself; and we know at present very little of the variations in the phagocytic activity of various leucocytes. Add to these things the consideration that we know little or nothing of the modifying influences exerted upon the phagocytosis by other immune bodies undoubtedly present in the serum, and it does not seem extravagant to assume for opsonic estimations an error of at least from 20 to 30 per cent. Whether this

error can be diminished sufficiently to make extended use of opsonic estimations by Wright's technique of real value is a matter which only the future can decide, but at present it seems unlikely when we consider how much of it is due to entirely uncontrollable influences rather than to imperfections of technique. Furthermore, it will have to be shown that in estimating a subject's immunity we are justified in making the matter of phagocytosis the sole standard of judgment with disregard of the various other immune bodies in the serum. The situation is in much analogous to that which existed when the degree of agglutination in typhoid fever was supposed to be entirely parallel with the degree of immunity.

Much work remains to be done before the therapeutic value of opsonins can be defined. Withal, it must not be forgotten that we are really dealing with two entirely separate questions when we discuss Wright's work on opsonins and his therapeutic efforts with specific bacterial emulsions, and even should the former investigations be shown to be of purely academic interest the revival of efforts toward active immunization inspired by the latter may still prove of inestimable practical value.

THE GAMETOID THEORY OF CANCER.

At a recent meeting of the Liverpool Medical Institution (*Lancet*, February 16, 1907) C. E. Walker presented a paper on this subject. He explained that as all living matter existed only in the form of cells, all problems of living phenomena must ultimately be cell problems. As all multicellular organisms, whether plants or animals, originated from a single cell (the fertilized ovum), the potentiality of all the cells subsequently produced from it was contained in the fertilized ovum. The author noted that the reduction in the number of chromosomes to one-half of the number found in the cells forming the body tissues, observed as occurring in sexual cells, might be compared with a similar phenomenon occurring in the cells making up malignant growths.

Over ten years ago various observers described the occurrence of division figures in cancer which possessed all the peculiar characteristics of the heterotype divisions; that is, the form of division in which the number of chromosomes was reduced to one-half of the normal number found in the body cells. A diagram was exhibited showing the results of an indiscriminate counting of the chromosomes in the dividing cells of malignant growths. This diagram when compared with one showing the results of a similar counting of the chromosomes in the cells of a testis proved that the relative proportions of cells containing the full and exactly half the normal numbers of chromosomes was almost identical in malignant growths and in testes. It was shown that "Plimmer's bodies," so frequently described by various authors as being the parasite of cancer, were exactly similar in origin, in mode of development, and in structure to the archoplasmic vesicles found in the spermatids of certain animals, including all mammals, but never in any other normal cells of the body. Thus there was another direct parallel between the cells of malignant growths and those of normal reproductive tissue. Emphasis was laid upon the fact that cells that had entered upon the reproductive phase lived normally as parasites upon the parent organism, and that all such cells, whether in animals or in plants, were out of coordination with the rest of the body. A true fusion between leucocytes and tissue cells was described as being one of the earliest phenomena in the commencement of malignant growths. Reduction in the number of chromosomes to one-half of the somatic (body) number was described as taking place normally among the leucocytes, thus making it probable that certain generations of leucocytes went through a sexual phase.

Basing his views on the foregoing facts, Mr. Walker pointed out that the malignancy of certain tumors might be due to the cells forming there entering upon a sexual phase, and there living as parasites upon the parent organism, as such cells always did. On this supposition it would be necessary to seek the cause or causes which induced this change. This left the leucocytic fusion in the position of a mere coincidence of no material importance. On the other hand, this fusion itself would equally account for the peculiar qualities possessed by the cells of malignant growths. They would necessarily be out of coordination with the parent organism, and would live as parasites upon it. Moreover, that some of them should enter upon the sexual phase was exactly what would be likely to happen. Here it would be necessary to find out under what conditions the fusion between the leucocytes and tissue cells was possible. It might be due to some change in either or both of the two kinds of cells.

THE BIER TREATMENT OF MASTITIS.

The beneficent action of Bier's suction treatment of inflammatory processes has already been recorded many times. The possibilities of the method in skilled hands appear to be very great, but it is also certain that when improperly used the results are likely to be discouraging and even directly injurious. Hartman (*Münchener medizinische Wochenschrift*, February 5, 1907) in discussing the suction treatment of mastitis refers to a reported case in which on the first application of the glass bell the pain caused was so intense that the patient fainted. The instrument used had a diameter of only 5 cm., whereas the inflamed area was as large as the palm of the hand, and had a fluctuating abscess in its center. Naturally the pain caused by the pressure over this acutely sensitive spot was extreme, whereas when correctly applied the suction gives marked relief from pain. Hartman says that the three commonest errors in the use of the suction treatment are the application of bells that are too small, the omission of early incisions, and discontinuing the suction too soon. In treating mastitis the diameter of the bell should never be less than 10 cm., and frequently one having a diameter of 15 cm. may be required. If there is fluctuation a very short incision under ethyl chloride anesthesia should be made. Hartman recommends daily sessions in which suction is applied four or five times during a space of five minutes, with an interval of from three to five minutes between the applications of the instrument. At the close of each session milk is drawn from the affected gland by means of a small bell placed over the nipple, and a wet dressing of aluminum acetate is applied. It is

usually unnecessary to leave any drainage material in the wound, though the insertion of a small tube may facilitate the aspiration of discharge while the suction is being applied. Hartman reports in detail the histories of twelve cases of mastitis in which this method was applied, and he considers that it represents a decided advance in the treatment. Pain and fever are lessened, and early cases are aborted in from three to five days without any incision. If abscess formation has commenced small incisions effect a cure in from four to seven days, though the average time is sixteen days. The cosmetic and functional results are excellent, and surpass those obtained by any of the older forms of treatment. In dealing with the subacute indurated forms of mastitis which do not go on to suppuration, the passive hyperemia produced by the suction treatment is less satisfactory, and the use of wet dressings followed later by massage is in many cases far preferable.

The Early Diagnosis of Lead Poisoning.

While lead poisoning in its more advanced stages is ordinarily accompanied by so characteristic a symptom complex as to make its diagnosis a matter of no very great difficulty, in early cases the conditions may be extremely hard to recognize. One of the most reliable evidences of plumbism, the detection of the metal in the urine, is unfortunately scarcely within the scope of the practitioner's laboratory, owing to the somewhat complicated and very time-consuming chemical manipulations it requires. Even in skilled hands negative results are common, and Frey (*Deutsche medizinische Wochenschrift*, February 7, 1907) states that Seiffert in the course of seventy-three analyses of the urine of tin refiners exhibiting the most varied symptoms of intoxication discovered lead in only 15.6 per cent. The chemical investigation of the urine therefore does not furnish a satisfactory means of diagnosis for mild or early cases. The granular degeneration of the red blood cells described by Grawitz some years ago seems to be of greater assistance, however. It consists in the presence in certain of the red blood corpuscles of minute particles having a strong affinity for basophilic dyes, so that in a blood preparation stained with one of the methylene blue solutions the cells in question present varying numbers of minute bluish points. Frey, also working among tin miners and refiners, arrived at the conclusion that in this peculiarity of the erythrocytes a most useful diagnostic indication of incipient blood poisoning was to be found. The other conditions in which it is likely to occur, such as cancer, pernicious anemia, intestinal putrefaction, and sepsis, can usually be excluded without difficulty, but the possibility of their occurrence must be kept in mind. The value of routine blood examinations with this appearance in view is very great, as in this way individuals may be excluded from the more dangerous forms of work until the disappearance of the basophilic granulation indicates that for the time being the danger of lead poisoning is over. As the granules in the red cells usually appear before the other symptoms have become characteristic, if the blood of those engaged in occupations that involve danger of plumbism is watched carefully the severer forms of intoxication can very often be forestalled. There is also another and very useful application of this discovery in that by frequent blood examinations one may very accurately estimate the degree of success of any therapeutic measures that may have been instituted.

Electricity in the Treatment of Heart Disease.

Comparatively little attention seems to have been paid to the use of electricity in its various forms in the treatment of cardiac affections, but in a recent article an Italian writer, Galli (*Gazzetta degli Ospedali*, No. 153, 1906) refers to the value of this measure as an accessory to other methods, including drugs and physical agents, which are commonly employed. There has existed more or less of a prejudice against electricity, because animal experiments have shown that faradization of the heart produces diminished heart action, incomplete contraction of the ventricles, reduction of the blood pressure, and finally paralysis of the organ. These results seem to have been borne out by observations made in the human subject, although this opinion has been somewhat revised by a further study of the effects of the galvanic, high frequency, and alternating forms of current. The galvanic current, for example, was used by Galli in the form of complete and local baths, which correspond in their effects to the carbonic-acid baths and may be substituted for the latter in certain cases. The alternating-current baths may be employed in those cases where compensatory disturbances of a severe type exist which are constant even without exertion on the part of the patient. The faradic baths, however, seem to have a better effect in anemic nervous patients who are afflicted with diseases of the vessel walls and also present renal symptoms. In otherwise strong individuals whose vessels and kidneys are in good condition, the sinusoidal current seems preferable and quite harmless. An interesting fact about both of these currents is that they appear to possess the property not only of reducing abnormally high blood pressure, but also of bringing back abnormally low pressure to the normal condition in a manner similar to that accomplished by digitalis. A general application of the high-frequency current reduces, and the local application of the same elevates, blood pressure. Another effect which is well marked in the use of the electric currents for the purposes noted is the favorable action on the various states of physical and psychical depression which are prone to occur during the course of chronic heart diseases.

The Serum Treatment of Dysentery.

Since Shiga's communication on this subject in 1898 numerous other observers have published reports on the treatment of dysentery by means of antitoxic serums. Although the conditions under which the individual observations were made have varied in more or less important particulars, such as the severity of the cases and the manner of obtaining the serum, on the whole the conclusions of these experimentors have been favorable to the method. One of the most recent papers on this subject is that of Skschivan and Stefansky (*Berliner klinische Wochenschrift*, February 11, 1907), who in the summer months of the preceding year treated by means of a serum fifteen cases of dysentery occurring in Odessa. The serum used was antitoxic, and had been obtained by a year's immunization of a horse with injections of the filtrate from cultures of the Shiga bacillus. The patients were between the ages of nineteen and forty-six years, and in seven the disease was of severe type, while in the others it was of moderate gravity. Every effort was made to render the effect obtained by the serum as conclusive as possible, and practically no other reme-

dial measures of any sort, except, of course, the rest in bed and suitable diet, were resorted to. The effect of the injections was manifest within two or three days, a distinct diminution in the progress of the disease, as shown by the decrease of pain and tenesmus, and reduction in the number of movements and improvement in their character being promptly noticed. In three to four days the stools had become diarrheal, and usually soon returned to their normal character. The authors therefore ascribe a very distinct and active remedial quality to the serum, and recommend that its use be more widely resorted to, especially in dealing with dysentery in children. Complications due to the serum, such as erythema and joint pains, were observed in two cases, but apparently were not of a serious character.

The Passage of Mercury from Mother to Fetus.

The question of the transmission of drugs and other substances from mother to fetus through the medium of the placental circulation continues to hold the attention of investigators on account of its great practical interest and value. It has been variously claimed that mercury among other things is able to pass through the placenta and be distributed through the fetal organs in a manner similar to that which takes place in the adult. Conti and Zuccola (*Gazzetta degli Ospedali*, No. 153, 1906) believe, as the result of their recent experiments, that mercury as such cannot pass through the placenta in the manner indicated, and that the effect which has been observed in the fetus is brought about in a different manner. In their tests they made use of a saturated solution of sulphureted hydrogen which had been acidified with nitric acid, and also examined the tissues microscopically. The experimental subjects included not only human fetuses, but also those of guinea pigs and rabbits which had been poisoned with bichloride of mercury injections. The three human fetuses were the products of syphilitic mothers who were undergoing mercurial treatment for their disease. In the experimental animals mercury in the form of a sulphate could readily enough be demonstrated in the various organs by the test indicated, but no such result was obtained in those of the offspring. The meconium of the human fetuses gave rise to a positive reaction, but this could not be confirmed by a later examination of the intestinal tract. The writers believe that in previous investigations the demonstration of the mercury in the fetal tissue was based upon imperfect and false technique. No definite proof has been brought forward of the actual presence of the drug in the fetal organs, and the therapeutic effect which has been observed may be explained, according to Conti and Zuccola, by the fact that the mercury has caused the development in the cells of the maternal organism of substances which have the property of exerting a neutralizing influence on the pathogenic factors in the fetal tissues.

The Relation of the Stomach to Labor Pains.

The fact has long been appreciated that a certain nervous relation exists between the uterus and the stomach which manifests itself in a variety of reflex phenomena. This is well shown during the course of pregnancy, not only the early months, but, as demonstrated in a recent study by Kehrer in the *Beiträge für Geburtshülfe und Gynäkologie*, Vol. 10, No. 2, up to the time of labor itself. Overdistention of the stomach or a gastric catarrh seems to exert a well-marked inhibitory effect on the labor pains, prolonging the periods of cervical dilatation and expulsion and thus leading to exhaustion of the mother and possible asphyxiation of the fetus. Spontaneous or induced vomiting will change this condition at once, and, according to Kehrer, may render operative delivery in certain cases unnecessary. If the ordinary means of inducing vomiting are not successful, the writer advises gastric lavage, although the effect of this is less certain. Another interesting point which is brought out in this paper is the fact that labor pains rarely come on during the afternoon because the stomach is usually filled at this time or digestion of its contents is going on, this condition acting as an inhibitory influence on the production of the labor pains.

News of the Week.

What a Medical Society Should Be.—Dr. Joseph Decatur Bryant, ex-President of the Medical Society of the State of New York, but President-elect of the American Medical Association, is apparently opposed to boss rule in medical organizations. In the course of his Presidential address, delivered at the recent meeting of the State Society, he remarked: "It [the State organization] is a free government in the complete sense of the expression, one in which the humblest members of the most cheerless stations of the State have equal privileges with those of exalted station in the midst of wealth and power; one in which the officers are your servants and not your masters, unless *you* so will it to be, and from whom you have the right to demand at the proper time, and in a suitable manner, a complete accounting of the status of their respective stewardships, and which, when wisely required, they have no right to decline. And in all other respects, your rights and privileges cannot be overshadowed by those of another unless you, yourselves, lend aid to the eclipse."

Lieutenant Carroll's Promotion.—The Senate bill raising Lieut. James Carroll of the Army Medical Corps to the rank of Major, in recognition of his services to science in the study of yellow fever, passed the House last week. At a meeting of the Nebraska Academy of Medicine recently held in Lincoln a committee of five was appointed to make an effort to secure a Nobel prize for Dr. Carroll. The members of the committee are Drs. S. R. Towne, A. S. von Mansfelde, H. B. F. Ward, R. H. Wolcott, and H. W. Orr.

State Pure Food Bill.—A Pure Food bill, which contemplates cooperation between the State and the Federal government in the prosecution of violations, and which in most of its details follows out the provisions of the Federal statute on the subject, has been introduced in the New York State Assembly. The bill takes from health officers most of their duties relative to detection of violations of the health law so far as foodstuffs are concerned, and transfers them to the State Commissioner of Agriculture.

The Milk Question.—At a meeting held last week in the United Charities Building, the New York milk committee expressed its opposition to the general municipal pasteurization of the entire milk supply, but favored the pasteurization of milk in feeding bottles for infants as the best means for reducing infant mortality in summer. Special emphasis was laid on the importance of establishing infants' milk depots before next June, for which the cooperation of private philanthropy and of the city authorities should be sought. A committee was also

appointed to seek to secure the cooperation of the State Board of Health and of the Department of Agriculture in relation to the destruction of tuberculous cattle, and greater activity of local boards of health in reference to reporting cases of communicable diseases in persons on farms or handling milk. The same committee was instructed also to oppose the ordinance now before the Aldermanic committee and the Reece bill at Albany. A letter from Commissioner Darlington was read, in which he stated that he was opposed only to compulsory pasteurization of all the city milk, but not to requiring the pasteurization of such milk as could not otherwise pass inspection. The meeting of the Section on Public Health of the New York Academy of Medicine on March 12 will be devoted to a discussion of the city milk supply. The following papers will be presented: "Milk as a Carrier of Infection," by Charles Harrington, M.D., Secretary Massachusetts State Board of Health; "Pasteurization: The Advantages and Disadvantages to the Consumer," by Rowland G. Freeman, M.D., of New York; "Pasteurization: The Advantages and Disadvantages to the Municipality," by Joseph Roby, M.D., Rochester, N. Y., Deputy Health Officer; "Current Misstatements and Fallacies Regarding the Milk and Milk Supply of New York City," by William H. Park, M.D., of New York. The discussion will be continued by Drs. L. Emmett Holt, Walter Bensel, and Linsly R. Williams.

Hudson River Ice.—Steps are being taken by the Merchants' Association's Committee on Pollution, to prevent further harvesting of ice in the Hudson River near the mouths of Rondout and Catskill Creeks. This section of the Hudson River is regarded as a particularly dangerous one, as the nearby village of Catskill is suffering from a typhoid fever epidemic, and ice is being cut from sections of the river which are practically at the mouths of both Rondout and Catskill Creeks.

Suicide Bureau in New York.—At the Salvation Army bureau for preventing suicide, organized last week for the purpose of giving good advice and, where needed, material help to those contemplating self destruction, eighteen would-be suicides applied on the first two days. Similar bureaus have been in successful operation in London and St. Louis for some time, and others are to be started in Boston, Cleveland, Chicago, Atlanta, Kansas City, Minneapolis, and San Francisco. One girl who applied to the bureau was not thinking of committing suicide, but needed skin to be used for skin-grafting a deep wound in her father's neck. The *Sun* states that when the request was made known, in a short time there were thirty volunteers among the young men of the training and industrial school ready to part with a portion of their cuticle.

Work of the Children's Hospital Society of Chicago.—This society in its existence of four years has done a far-reaching work, and has been the means of improving the health and saving the lives of many babies in the crowded portions of the city. The society's first work was to found a Milk Commission, and it has distributed 1,043,175 bottles of the cleanest, purest and best milk that any cow could give, it is said, which have been of untold value to sick and convalescent infants. The latest undertaking of the society is to aid in getting the State Legislature to appropriate money for the establishment of a State epileptic colony. For this purpose, under the auspices of the society, Dr. W. C. Spratling, superintendent of Craig Colony for Epileptics, New York, recently gave an illustrated lecture in the Senate Chamber at Springfield, before the members of the Legislature. It is claimed the colony as proposed will be almost self-supporting. The State Board of Charities has asked the Legislature for $365,000 with which to found an epileptic colony.

Contagious Diseases in Chicago.—According to a recent report of the Chief Medical Inspector of the Chicago Health Department, Dr. Heman Spalding, cases of diphtheria, measles, and scarlet fever show a decided and substantial reduction in number. This reduction has been steady and rapid, dating from the week the new medical inspectors were put to work. This work speaks for itself, and nothing can be said that emphasizes the necessity of a permanent medical inspection corps equal to the results of these few weeks of medical inspection of schools.

Typhoid Fever on the "Connecticut."—The battleship *Connecticut* reached this port last week from Guantanamo with between thirty and forty of her crew ill with typhoid. The first cases appeared early in February, and when the severity of the epidemic became apparent, the vessel was ordered north in order that the patients might be transferred to the Naval Hospital at the Brooklyn Navy Yard. The origin of the infection has not been discovered. It is stated that the disease is not of a severe type and that none of the men are in a serious condition.

Plague in East Africa.—The German papers report that two cases of plague have occurred at Muanza, German East Africa, and also that one case of plague was discovered on a British steamer which arrived recently at Muanza. The colonial authorities are making strenuous efforts to prevent the spread of the disease.

Experimenter Contracts Plague.—A cable despatch from Kronstadt states that Dr. Schreiber, surgeon of the Second Siberian Regiment, who had been experimenting with living organisms in connection with researches on bubonic plague, has contracted the disease and has been isolated in the fort where he carried on his work.

Overcrowding at St. Vincent's Hospital.—Ordinarily the accommodations in this hospital serve for the reception of about 400 patients, but lately, owing to a great increase in applicants of all classes, there have been 600 patients at a time in the hospital. Cots have been put up in every available spot, and both the house staff and nursing corps are severely overworked. An unusually large proportion of the cases in the hospital are of pneumonia.

Street Spitters Arrested.—Ten persons were arrested on one day last week by members of the Sanitary Squad for spitting in the streets. All the arrests were made on Fifth avenue, between Fourteenth and Sixteenth streets. After arraignment in the Jefferson Market Court, the prisoners were discharged with a warning.

The State Registration of Nurses.—The Pennsylvania State Committee on Nursing, which has for its object the regulation and advancement of nursing and the fostering of a proper relation of nurses to the medical profession and the community, has issued a statement relative to the bill now before the Pennsylvania State Legislature providing for the registration of nurses. The enactment of such a measure is deprecated on the ground that State law for the registration of nurses is not only unnecessary, but is positively harmful. The tendency of such a law is to lead the average nurse to assume too much, and to lessen her usefulness. It is

further stated that such a law would be a menace to the community, and that under its provisions the presence of nurses in the sick room might be a positive danger. The maintenance of a uniform scale of charges of $25 or $30 a week would also, it is claimed, result in detriment to the mass of the people who cannot afford to pay such rates. The ultramedical training given nurses in many institutions is also criticised.

Hospital Transfer Bill Passed.—The State Senate last week passed Senator Sohmer's bill making it a misdemeanor to transfer patients in a critical condition from one hospital to another. The bill also compels superintendents of New York city hospitals to admit all patients brought to them if they have room and the patients are not suffering from contagious diseases.

The Kings County Grand Jury for February has adopted a resolution calling on the Grand Jury for March to look into conditions in the Brooklyn Hospital, alleging that the patients in that institution do not receive proper attention from the orderlies unless they bestow gratuities liberally. The superintendent of the hospital has denied that any such condition existed.

Misericordia Hospital to be Enlarged.—Plans have been filed for a $125,000 addition to the Misericordia Hospital at Avenue A and Eighty-sixth street, conducted by the Sisters of Misericordia. A five and six-story extension is to be added, with a frontage of 123 feet and a depth of 54 feet, having a façade of brick and ornamental stone. Part of the addition will be fitted as a home for the sisters, with a chapel attached. The building will also have a roof garden.

For a New Dispensary.—The recently organized Brownsville Hebrew Dispensary Society will hold a public meeting on March 18 to appeal to the residents of Queens County for the establishment of a dispensary in that section because of the large number of poor persons living in the district.

Tuberculosis Camp in Plainfield.—The tuberculosis committee of the Plainfield Clinical Society has formed a permanent organization and decided to establish a tuberculosis camp in Plainfield for the outdoor treatment of consumptives.

A Chair of Hydrotherapy at Columbia.—At a meeting of the Trustees of Columbia University on Monday of this week, it was voted to establish a chair of hydrotherapy at the College of Physicians and Surgeons. Funds for this purpose, it was stated, will be provided by an anonymous donor.

Dr. Doty's Appointment Confirmed.—The appointment of Dr. Alvah H. Doty as Health Officer of the Port of New York was confirmed by the Senate on February 28.

Dr. Samuel G. Dixon of Ardmore, President of the Philadelphia Academy of the Natural Sciences, has been reappointed, by Governor Sturat, State Commissioner of Health of Pennsylvania.

Dr. Henry Heiman has been elected adjunct professor in the department of pediatrics of the New York Polyclinic.

Dr. Emmet P. North of St. Louis has been appointed to fill the vacancy made by the death of Dr. A. V. S. Brokaw, chief surgeon of the United Street Railways Company of that city. He will be called the chief medical director, and has appointed a corps of assistants located in various parts of the city. Dr. North has served in the City Hospital, the Missouri Pacific Railroad Hospital, and the South Side Dispensary, and has for some time been a division surgeon for the United Railways Company.

The Interlude of Cancer.—In the article with this title by Dr. Beard of Edinburgh, in the MEDICAL RECORD of February 2, a misprint occurs in the first column, in which Freiburg, Baden, was made to read Freiburg, Berlin. On page 174, under *Embryomata*, the last sentence begins: They are now endowed, etc. For "now," one should read "not."

Against Vivisection.—A bill has been introduced into the Pennsylvania Legislature making it unlawful to vivisect or experiment on any living animal for any purpose, scientific or otherwise, and fixing as a penalty a fine of from $100 to $500, or imprisonment for from 30 to 60 days, or both.

The Society of Tropical Medicine, which has existed for a few years, and is especially active in Philadelphia, will hold its first meeting in New York on March 29, 1907, at 8:30 P.M., at the Academy of Medicine.

Association of American Medical Colleges.—The next annual meeting of this association will be held in Washington, D. C., May 6, the day before the opening session of the American Congress of Physicians. The Hotel Raleigh is to be used as headquarters.

The Harvey Society Lectures.—The tenth lecture in this course will be given at the New York Academy of Medicine on Saturday, March 9, at 8:30 P.M., by Dr. Friedrich Müller, Professor of Medicine at the University of Munich, Germany. Subject: "Neuroses of the Heart." This is the last lecture of the present year's series.

The Lisbon Congress.—The Portuguese members of the Fifteenth International Medical Congress, held last year, have presented Professor Miguel Bombarda with a gold medal and an address expressing their appreciation of his services as organizing secretary of the congress.

Statistics Relating to School Children.—The figures of a still unfinished census being taken in this city under the direction of the State Department of Education show that at least 20,000 children of the proper age are not attending school, as is required by the compulsory education law. The census, taken by the police in October, November, and December, includes all persons between four and eighteen years of age in the greater city. Of these, 4,371 are working illegally; 4,787 are kept at home illegally; 294 are truants; 8,402 are not attending evening school, as required, and 1,449 are physically unable to attend school. The actual total of non-attendants found to date is 19,303.

The Late Dr. Julia W. Russell.—The following resolutions have been adopted by the Women's Medical Association of New York City: *Resolved*, That it is with a deep sense of personal and professional loss that we record the death of Dr. Julia Wallace Russell. *Resolved*, That we her friends and fellow-workers bear testimony to her high character and useful life. *Resolved*, That we express our appreciation of the honor she did our profession as a practitioner and as the founder of a hospital for women and children. *Resolved*, That a copy of these resolutions be sent to her family with an expression of our sympathy with them in their great bereavement. *Resolved*, That these resolutions be recorded in the minutes and be published in the medical journals. (Signed) Sarah J. McNutt, M.D., Mary D. Hussey, M.D., Committee.

The Late Professor Herman Cohn of Breslau, well known as an ophthalmologist, bequeathed the sum of 10,000 marks to each of the universities of

Heidelberg, Tübingen, and Breslau, the income to be used for prizes for research in ophthalmology.

Obituary Notes.—Dr. Frederick G. Merrill of this city died on February 24 at the home of his brother at Skowhegan, Me., at the age of fifty-two years. Dr. Merrill was born in Harmony, Me., and, after graduating from Bellevue Hospital Medical School in 1879, began practice in this city. He was for some time on the staff of the Trinity corporation.

Dr. John G. Keith of Leadville, Col., died on February 16 in St. Louis, at the age of sixty-five years. Dr. Keith was formerly a resident of St. Louis, but for eighteen years had practised in Leadville. He was a veteran of the Civil War.

Dr. Herbert B. Williams of Gladys, Va., died on February 20 of typhoid fever, at the age of twenty-nine years. He is survived by his brother, Dr. Walter Williams of Brookneal.

Dr. L. W. Bliss of Saginaw, Mich., died suddenly of heart failure on February 20 in San Antonio, Tex. Dr. Bliss was born in Madison County, N. Y., in 1836, and, after serving through the Civil War as surgeon of the Tenth New York Cavalry, settled in Saginaw in 1866. He was prominent in the city's public affairs, and was Mayor of Saginaw for three years. In 1891 he was president of the State Medical Society.

Dr. W. J. Kendall of Upperville, Va., died on February 20 of pneumonia after an illness of a week. He was forty-five years of age, and was a graduate of the Virginia Polytechnic Institute and the Baltimore Medical College.

Dr. Joseph A. Loeb of Stamford, Conn., died of typhoid fever on February 24 after an illness of three weeks. Dr. Loeb was graduated from the Yale Medical School in 1902, and had practised for a time in New Haven.

Dr. Makel A. Southworth of San José, Cal., died on February 16 at Wright's Station. Dr. Southworth was a native of Herkimer, N. Y., and had been a resident of San José since 1893. He had been county health officer and president of the Board of Pension Examiners. During the Civil War he served as a surgeon, and for a time had charge of the yellow fever quarantine station at New Orleans.

Obituary.

GEORGE BINGHAM FOWLER, M.D.

NEW YORK.

Dr. George B. Fowler died at his residence in this city, on March 6, from gastric disease, at the age of sixty years. He was born in Montgomery, Ala., in 1847, and was the only son of a physician, Dr. Edmund Fowler, of that place. He was sent to school in Westfield, Mass., and later was graduated from the "Free Academy," now called the College of the City of New York. He studied medicine at the College of Physicians and Surgeons in this city, obtaining his degree therefrom in 1871. His hospital experience was gained as an interne at Bellevue. He was for a number of years after graduation associated with the teaching staff of the institution, first as curator of the museum and then as instructor in physiology. For a time he was an adjunct professor at the New York Polyclinic, and later was called to a professorship of clinical medicine at the New York Post-Graduate School and Hospital. In 1895 he was appointed Health Commissioner of the city of New York by Mayor Strong, and Commissioner of the State Board of Health by Governor Morton. He was for two terms president of the Medical Society of the county of New York, and helped establish the Tenement House Commission in this city. He was associate editor of the *American Journal of Obstetrics* from 1880 to 1886, and he was one of the founders of the *Dietetic Gazette*. He was a member of the County and State Societies, of the Academy of Medicine, and of the American Therapeutic Society, and was, at the time of his death, consulting physician to the Bellevue and the French Hospitals.

SIR WILLIAM HINGSTON, M.D.

MONTREAL.

Sir William Hingston, M.D., one of Canada's most distinguished physicians and philanthropists, died suddenly on February 19 at his home in Montreal. He was born near Huntingdon, Que., January 29, 1829, and was educated at the Montreal College, receiving his medical degree from McGill University. He completed his medical training in the University of Edinburgh, and on his return to Montreal in 1853 began to practise in that city. He speedily rose to prominence, and for many years was the leading surgeon of Montreal. He had occupied numerous official positions, among them that of governor of the College of Physicians and Surgeons of Lower Canada, of Mayor of Montreal, and of President of the Medico-Chirurgical Society of Montreal. During his mayoralty he organized the local and provincial Board of Health, and in 1895 was knighted for distinguished medical service. He was a fluent writer, and, in addition to many journal articles, wrote a work on the climate of Canada and its relations to life and health, which is considered one of the best on the subject. He was a member of the Royal College of Surgeons, Edinburgh, and had received many honorary degrees and titles from universities and medical associations in this country and Europe.

Correspondence.

THE SCIENTIFIC CRITERION OF A MALIGNANT TUMOR AND THE NATURE OF JENSEN'S MOUSE-TUMOR.

To the Editor of the Medical Record:

Sir:—In your issue of February 9 (p. 237) Mr. W. Roger Williams, F.R.C.S., in characteristic fashion accuses me of "gross misrepresentation" without citing instances. It is so easy to do that! He adopts the old familiar attitude he is so fond of taking up with an opponent, that of mistaking bald assertions for arguments and scientific evidences. Possibly the statement he complains of is that "scientific reasons are not contained in the original report of his lecture in London," etc., and this he twists into "Dr. Beard's special point against me is that I have not adduced my scientific reasons for denying the cancerous nature of Jensen's mouse-tumor." No doubt he adduced what he mistook for scientific reasons, but they were such as would not bear scientific scrutiny. I am a scientific investigator, a searcher after truth, and I never misrepresent any person or anything. That I leave to transparently anonymous writers in British scientific and medical papers. Regarding his recent letter I repeat the statement. Scientific reasons are *not* contained in his letter to the Medical Record of February 9. On page 238 he recites what he terms "the plain facts," and gathering them together in a bundle at the close of his letter, he flings them at my head as "crucial for diagnostic purposes." The "plain facts" he names, if they be facts, are such mainly because he says they are. They are not like axioms of Euclid or laws of mathematics. Most, if not all of them, are open to challenge not only by me, but by many other scientific workers. I will pass them in brief review.

Neither in Edinburgh, nor in London, nor in Copenhagen, has the Jensen mouse-tumor been found to be contagious at all! It is only in places where a new cancer-parasite is in keen request and in urgent demand

that Jensen mouse tumor acquires contagious properties. These are in direct proportion to the researcher's faith in cancer-parasites! The "contagious venereal malady" of bulldogs is a true sarcoma. On the facts revealed by the work of Dr. Anton Stricker and of Dr. H. Wade, in agreement with the former, I stated this a year ago in the Pathological Club here. The latter observer denied its truth, and in one of their reports last year the officials of the Imperial Cancer Research Fund "demonstrated" at great length that it was an infective granuloma. Now, because Mr. Shattock has arrived at this conclusion of its sarcomatous nature from his own work, and especially from the occurrence of true metastases, the foregoing supporters of Mr. Roger Williams's view with commendable and astonishing celerity have abandoned their position! The artificial propagation of human cancer, a horrible experiment to think of, has never been tried on any scale in the least comparable to that of the Jensen tumor, which has been inoculated into countless thousands of mice. Therefore this comparison is invalid. The transplantation experiments were humorously summed up by a prominent London physician as follows: "Some mice do take the cancer, and some don't. If you only go on long enough, those that don't become those that do. You can never be sure, and you never know where you are." It is not a scientific argument to deny that spontaneous cure has ever been observed in human cancer. It has not been observed in spontaneously arising or original cancers in mice. An artificially propagated cancer may quite conceivably behave otherwise than a sporadic cancer. What chance is there of spontaneous cure in human cancers being observed when practically every cancer which can be operated upon is removed at least once, if not six or seventeen times? Possibly for Mr. Roger Williams's special benefit, one such case was described in the *Journal of the American Medical Association* for February 9, page 481. Of course, of this as of other cases, it will be said that it was not a malignant tumor at all, "whatever its real nature." To assert that Jensen's mouse-tumor does not cause cachexia appears to me to be equivalent to a denial that it has an influence upon the nutrition or the metabolism of its host, which is not true. Certainly it forms no metastases, but not all human cancers do this. Finally, the Apolant and Ehrlich mouse-tumor is *not* Jensen's tumor, but another sporadic neoplasm, not hailing from Copenhagen. What these observers noted all goes to demonstrate the identity of cancer and sarcoma. When the above are summed up, what is left of Mr. Williams's "crucial" test? Nothing at all worth picking up!

But more remains to say. My opponent cites some published observations* on the occurrence not only of trypsin, but of amylopsin and of lipase in carcinoma cells from the pancreas-gland! Does Mr. Roger Williams mean to suggest that, because these observations are published, and in the pages of the *Journal of Anatomy*, they are of necessity true, or indeed, that they can contain a particle of truth? Will he or any surgeon maintain that there is or can be in this visible universe, as it is constituted, a particle of scientific evidence demonstrating that the living cells of any cancer can secrete the pancreatic enzymes, trypsin and amylopsin? As of other scientific journals, so also of the *Journal of Anatomy* it can be said that its volumes contain papers devoid of all scientific truth. How could it be otherwise in a world where no sooner does a scientific investigator reach a certain conclusion and publish it than some other "observer" either tries to annex the find, as, of course, happened with my cancer results, or by some curious human mental process arrives at the very opposite conclusions? Scientific men are fortunate if they have then to deal only with these two "views" and not with a score of rival ones. One very prominent British physiologist in his book lays it down that the fresh pancreas-gland contains little trypsin, but much amylopsin. A scientific man, skilled in ferment research, told me not very long ago that there was plenty of trypsin, but hardly any amylopsin it it; while a third, a scientific man and distinguished physician, whose conclusions I adopt because I have seen and tested his extract of it, maintains that *both* enzymes are present in abundance! Waring does not go the length of stating that he found pancreatic enzymes in the specimens examined. It was reserved for Mr. Roger Williams to make this assertion! His words are "the same or similar ferments." This work is not in accord with the findings of Petry, or with the prolonged chemical researches of Bergell, Blumenthal, and Wolff in Berlin, who found that cancer-cells were easily digested by pancreatic ferments. The scientific work of these latter may not be stigmatized as "rather the outcome of *a priori* considerations." That verdict should be reserved for my opponent's "arguments," for these are never based in actual personal scientific researches in the laboratory. To refer to the work of these German investigators in terms such as those employed by Mr. Roger Williams betrays an utter failure to realize the existence of a science of physiological chemistry. Now, although it is not common sense to do so, let it be supposed that Waring *did* find trypsin and amylopsin in certain cancer-cells. What then? Was it by means of these ferments that these cancer-cells were eroding the patient's liver and causing his death? If not, was the cancer-ferment, malignin, the culprit? If so, what were trypsin and amylopsin doing *en cette galère?* Mr. Williams cannot be aware that large quantities of potent pancreatic enzymes can be, and have been, injected beneath the skin of a healthy dog; that trypsin in quantity could then be detected in its urine, and that the only effect noted upon the dog was increase in weight. None of the internal organs were injured (Dr. S. N. Pinkus). If Waring actually found trypsin and amylopsin in pancreatic carcinoma cells, which had traveled to the liver, then in this case these enzymes had attacked the liver-cells, which looked at scientifically is utter nonsense. Certainly, trypsin kills cancer-cells. That is in evidence in specimens taken from or cast off by several treated cases. Mr. Williams has only to read the American medical journals attentively to find it stated again and again. At this moment these effects of pancreatic ferments upon living cancer-cells have been seen by many prominent pathologists in New York. Really, the next wonder we may hear about from the Transactions of some learned society or from the pages of some scientific journal, may be that some cancer-cells produce bile, or excrete urea, or that in cancer of the breast the tumor cells, true to their (supposed) origin from mammary cells, the mythical "tumor germs" of my opponent, actually go the length of secreting—milk!

When it suits my convenience I will demonstrate that these assertions by Mr. Roger Williams contradict some of the elementary facts of organic chemistry, and that for these reasons also the statements are false. As to the existence of "any specific cancer substance," there are actual evidences of the occurrence of a whole array of such, and some of these evidences are extant. I decline to produce further evidences at this juncture, for an investigator has the right to choose his own time for publishing broadcast new findings and conclusions. That is part of the strategy of science! Not that this need of necessity disturb the serenity of Mr. W. Roger Williams, F.R.C.S., or of his colleague in Chicago! Having abolished the science of physiological chemistry, the annihilation of the elements of organic chemistry may turn out to be a very simple task! A new universe, in which cancer-cells regularly secrete the powerful pancreatic enzymes, trypsin and amylopsin, may then begin its evolution under their scientific auspices! In such an amazing field of research a Pasteur would find himself as much out of place as trypsin and amylopsin would be in living cells of any existing malignant neoplasms!

J. BEARD.

EDINBURGH, SCOTLAND.

*H. J. Waring, the Physiological Characters of Carcinomata, *Journal of Anatomy and Physiology*, Vol. 28, pp. 142-148, 1893-94.

LOCAL ANESTHESIA FOR NASAL AND AURAL OPERATIONS.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—That considerable interest is taken in the subject of local anesthesia for submucous resection, is shown from the number of communications I have received in relation to my article which was printed in the MEDICAL RECORD of February 23, and I wish to add to what I said: (1) That the exact proportions of cocaine and adrenalin chloride should be observed, namely, 10 grains cocaine, 20 drops adrenalin chloride (1 to 1,000). (2) The time to operate is when the membrane becomes scarlet, and not when it is blanched, as when cocaine alone is used. (3) Care should be taken to express any excess of solution out of the applicator, it is necessary only to have the cotton saturated and then to rub it on the membrane gently.

I also suggest the use of the solution in cases of paracentesis of the ear-drum, for which it acts as an almost perfect anesthetic, if allowed to remain in the ear some little time.

Through an inadvertence in my article in the issue of February 23 credit was not given to Dr. John Leshure, who first suggested this use of cocaine and adrenalin to me, and from the stimulus of this idea this (thus far) most desirable method of application was evolved.

F. E. MILLER, M.D.

OUR LONDON LETTER.

From Our Special Correspondent.

THE HUNTERIAN ORATION—ROYAL COMMISSIONS AND TUBERCULOSIS—LETTSOMIAN LECTURES ON CEREBRAL TUMORS—EPIDEMIC CEREBROSPINAL FEVER—PROFESSIONAL MISCONDUCT—GLASGOW UNIVERSITY—OBITUARY.

LONDON, February, 15, 1907.

THE Hunterian oration was delivered yesterday afternoon by Mr. H. T. T. Butlin before a considerable audience, and the festival dinner took place in the evening. The oration was in the main an examination of Hunter's objects in life and how he accomplished them. John Hunter saw, said the orator, long before the men of his time, something was seriously wrong with surgery, saw further what was needed to correct it, set himself in the prime of life the task of doing all he could to set the wrong right, and continued for the rest of his life to pursue that object, to the impairment of his health and the expenditure of his fortune. In 1748 a young man from the North arrived in London, but no one could have predicted that this young man would leave such a reputation as this celebration proved. He had to fight for everything he obtained. He saw that surgery rested on a frail foundation, and could not be carried further or practised with confidence so long as it had no firmer basis. Mr. Butlin expressed astonishment that Hunter could find time, amid all his multifarious pursuits, to carry on a large surgical practice, practise and take the first place as a hospital surgeon in London. But that was his only means of earning money, and money he must have for his scientific needs. His collection of specimens, prepared by himself, had grown so that he was obliged to build a museum for it. His last years were marred by broken health. He suffered, too, great anxiety because the catalogue of his museum was not completed. He died in 1793, but it was not until six years afterwards that Parliament purchased for £15,000 the museum on which he had spent all his spare time and ruined his health, and which he estimated had cost him £70,000. Eventually, the museum was presented to the College, and Mr. Butlin concluded his oration by asserting that one of the chief objects of the succession of college councils has been, not merely to maintain the Hunterian Museum, but to enlarge and perfect it, so that at this moment the Council could exhibit it as the best museum of its kind in the world.

At the dinner in the evening, the President of the College, Mr. Henry Morris, took the chair and proposed, in an appropriate speech, "the memory of John Hunter," the toast being drunk in silence. The health of the orator was afterwards proposed, and he briefly replied.

The opening of Parliament this week may suggest to optimistic sanitarians the hope of fresh legislation on the prevention of disease, but we are a long way from Disraeli's political cry, *sanitas sanitatum, omnia sanitas*, and what has passed since then is not encouraging. Politicians are more concerned with party than public health. Some who despair of Parliament have a strange confidence in Royal commissions. As I mentioned in my last, Mr. Dunn demanded one on cancer, and I might have added that Mr. Henry Sewill is advocating one on quackery. I have not much faith in Royal commissions as remedies for social evils. They seem to be a convenient method of shelving what governments cannot quite ignore, but do not want to be troubled with. Consider their uselessness in respect to tuberculosis. In response to urgent demands by the medical profession and sanitary authorities, a Royal commission was appointed in 1890 to inquire into the effect on human health of food derived from tuberculous animals. This commission labored for five years at the question, and in 1895 reported that tuberculous meat and milk did give rise to tuberculosis in man. Did the legislature proceed to protect the people from the indicated danger? Not at all. In 1896 another Royal commission was issued to inquire into the administrative procedures required for controlling this danger. This commission, like its predecessor, was composed of distinguished scientific authorities, who deliberated and inquired for two years, and reported in 1898 that various legislative measures were required, among them the appointment of qualified meat inspectors, notification of diseases in cows, and the enforcement of hygienic conditions in cowsheds, etc. Nine years have gone by since this report was presented, and not one of its recommendations has been carried out. In 1901 yet one more Royal commission was appointed, in response to the outcry produced by Koch's statement the year before that human and bovine tuberculosis were not identical. This last commission is still sitting to "Inquire Into the Relation of Human and Animal Tuberculosis." It has, however, published two interim reports, the first in 1904, summarized for you at the time, and the second only this month, and of which I gave you a brief notice in my last letter. Have I not justified my want of faith in the efficacy of Royal commissions? The consequences of this neglect of Parliament to deal with the prevention of disease are tragic. The absurdity of appointing commission after commission to inquire into the same subject, and putting report after report into convenient pigeon holes, must be obvious to all except governments and politicians absorbed in partisan contests.

That the public may yet be aroused to take a hand and compel attention to its dangers is perhaps possible on account of some disgusting revelations lately made—such as the sale of animals in the last stages of tuberculosis in open markets for paltry sums—such as 45s. and 50s. which a butcher paid for two cows, which he was proved in court to have proceeded to kill and prepare for sale for food. It is the same with milch cows; in markets where there is no inspection tuberculous animals can be sold.

The Lettsomian lectures for this year are being delivered by Dr. Ch. E. Beevor, and his subject is the diagnosis and localization of cerebral tumors. In the first lecture (on the 4th inst.) he observed that we have to depend almost entirely on the effects of pressure, and these may be either central or peripheral. They are mostly of the nature of pain, paralysis of action, or loss of sensation, and so the symptoms are mainly subjective. But some are independent of the patient, *e.g.* optic neuritis, paralysis of the ocular muscles producing strabismus, and the state of the reflexes. Headache, vomiting, and optic neuritis, Dr. Beevor said, were frequent in intracranial tumors irrespective of the position of the tumor. Headache fixed in one spot was some indication, particularly if attended with tenderness on pressure. If the headache was general, and accompanied by vomiting and optic neuritis, it was a help to diagnosis, but not to localization. Persistent pain, with tenderness, pointed to a superficial origin from the membranes rather than the cerebrum. Vomiting must be frequent and independent of food to be of any assistance, as it often attends migraine. Optic neuritis, with headache and vomiting, was one of the most reliable signs of tumor, but must be distinguished from the same symptoms in Bright's disease. Moreover, as Dr. Hughlings Jackson first showed, this neuritis might be intense, yet not interfere with vision, unless atrophy had commenced. It has now become of practical importance to be able to distinguish tumors near the surface accessible to operation from those too deeply seated. Even in these latter, relief could often be obtained by removal of a large piece of bone, so as to release the compressed brain from the pressure. The first effect of a tumor of the membranes pressing on the cortex was an epileptiform fit beginning in the part of the body representing the part pressed upon. A fit produced by a coarse lesion did not affect consciousness, but beginning locally it might become general, and then could not be distinguished from idiopathic epilepsy. The next effect of the pressure was paralysis, and that permanent on account of destruction of the cortex, loss of power then replacing the commencing spasm of the fits. Dr. Beevor then gave details of some cases in which the ascending frontal convolution, and others in which the ascending parietal convolution was involved, and said the question arose whether sensation was more affected in the latter than the former, and, if so, how far the difference would assist localization. So far as they went, these cases tended to show that parietal tumors, particularly those in the inferior part of the lobe, were more likely to have fits, beginning with a sensory aura, and to be followed by more extensive and permanent anesthesia and analgesia, than those in the frontal convolution, where the sensory changes were mere defective localization and loss of sense of position in the part first affected by motor spasm in a fit.

In the course of his lecture, Dr. Beevor referred to the history of localization, and mentioned that before experimentalists had established the principle Dr. Hughlings Jackson had reached the conclusion that unilateral and localized convulsions were due to irritation by tumors of particular convolutions of the opposite hemisphere functionally related to muscular movements. Dr. Jackson predicted that certain convolutions would be found excitable. His views were confirmed by the experiments of Fritsch and Hitzig in 1870 and Ferrier in 1873. It is difficult to realize, said the lecturer, that previously there was no such thing as localization, and one part of a convolution was supposed to have the same function as the rest. It was, in fact, only actual demonstration that overcame the opposition entertained against the idea of localization. Except Broca's center for speech, all our knowledge of localization has been obtained by experiments on animals. It is this research which has made possible the diagnosis of cerebral tumors, and with it the surgery of the brain. It is now over twenty years since Mr. Godlee (thanks to antisepticism) removed the first cerebral tumor in London. Sir Victor Horsley soon followed, and has since removed many, as have other surgeons. The practical importance of accurate localization has therefore become immense.

Cerebrospinal meningitis is causing uneasiness to health

authorities, and the feeling has extended to the people, as the newspapers report outbreaks of "spotted fever," as it is popularly called—a convenient name, though inexact, as the symptoms expressed are by no means constant. Cerebrospinal fever is used for the epidemic form, but the distinction is not commonly observed. The authorities do not exactly anticipate an epidemic in London, but the possibility of such an event cannot be ignored, and sporadic cases have been reported. Last evening the Medical Officer of Health for Lambeth reported to his Borough Council a case in his district in a girl six years of age. She was removed to hospital, the house disinfected, and the inmates are under strict observation. The Health Committee intend to recommend the London County Council at the meeting on the 26th to make the disease notifiable for a period of six months and to provide facilities for confirming diagnoses. The City Corporation is in advance of the County, for at the Court of Common Council yesterday it was stated the Port sanitary authorities had already made the disease notifiable, and the Port medical officers were keeping a very sharp lookout for any case that might occur, so that appropriate prophylactic measures might be instituted in season.

In Belfast, Dr. Baillie reported to the Health Committee yesterday 13 fresh cases during the week, with 8 deaths, and 19 patients in the hospital. The serum supplied from Berne had been used in one case, and was followed by much improvement, although that might have been only a coincidence. Of the total patients, 73, up to Wednesday 39 had died. In Dublin, 2 deaths have occurred and 2 cases remain in hospital. In Glasgow, 4 additional deaths were reported on Wednesday and 6 fresh admissions. In several Scotch towns cases have occurred. A case in Cumberland, fatal in twelve hours, is conjectured to have been contracted from persons who had arrived a few days before from Glasgow.

Professor Osler, being on a visit to Edinburgh last week, gave a lecture to the University medical students. He said in New York some 3,000 deaths had occurred in the last two years from the epidemic. The disease was not pandemic, but one of its peculiarities was to appear in widely separated places. Its mortality as an acute affection almost equaled that of plague. They knew of no disease which struck a patient with such lightning rapidity. It had probably the same degree of infectiousness as pneumonia in home epidemics. Many instances proved it could be communicated from one person to another. At present it was not widespread as an epidemic in Britain, and there was no reason why it should be. It was not likely to prevail beyond the winter season. As to treatment, it had been found that frequent hot tubs were a great comfort to patients. Prof. Osler thought it a hopeful feature that a serum had been prepared which had rendered monkeys immune, and it was not unreasonable to look for the elaboration of a similar serum for use in man.

"Conduct infamous or disgraceful in a professional respect" is not the same thing as "professional misconduct." Such is the dictum of Mr. Justice Warrington in a recent trial, after taking time to consider his judgment. Unless, and until this judgment is set aside by a superior court, such is the law, and it seems to add one more proof to the uselessness of the General Medical Council, which in the case tried had found a dentist guilty and removed his name from the register. The judge said the employment of unregistered assistants was not, so far as he could see, contrary to any rule of professional conduct, and advertising was allowed in the dental profession. There were other points of interest in the case, which was one to decide if one partner could terminate a partnership in which the articles gave him such power for "professional misconduct." A plain man would have supposed the phrase equal to the statutory term, and that the order of the Council should be received as sufficient evidence. Not so the lawyers, who have found another opportunity of profitable hair-splitting. The Medical Council must get fresh power from the legislature or sink into insignificance.

Dr. MacAlister is the new Principal of Glasgow University, notwithstanding the Secretary for Scotland's communique that the statement was "unauthorized." The next day he had to officially announce that the King had "approved" the appointment. Perhaps he was shocked at the press disregarding red-tape in its effort to be previous. Dr. MacAlister has received many academical honors and is a strenuous worker. He need not necessarily resign the Presidency of the General Medical Council. Sir William Turner held that office and at the same time the Principalship of Edinburgh University.

The death took place on Wednesday of Dr. J. E. Huxley, in his eighty-seventh year. He was a brother of the late Professor Huxley and formerly Medical Superintendent of Barming Health Asylum. He took his M.R.C.S. in 1843 and M.D., St. Andrew's, the next year.

OUR VIENNA LETTER.

(From Our Special Correspondent.)

THE FIRST SUCCESSFUL PLASTIC OPERATION ON THE CORNEA—CASES OF KIDNEY DISEASE—THE FAT DIGESTING POWER OF THE STOMACH—ECHINOCOCCUS CYST—POISONING WITH MALE FERN—SURGICAL TUBERCULOSIS.

VIENNA, January 30, 1907.

THE possibility of performing a plastic operation on the cornea was first suggested by Reisinger in the preceding century, but all attempts to graft corneal tissue from the lower animals to replace defects in the human cornea were unsuccessful. A partial, though only temporary, success was achieved by Sellerbeck, who in 1878 succeeded in transferring a corneal flap taken from the eye of a two-and-a-half-year-old child that had been enucleated owing to a glioma in order to repair the damage caused by gonorrheal ophthalmia in an adult. Healing took place, but on the twenty-first day the graft became cloudy and vision was again destroyed. Other attempts also failed and the idea of restoring sight in this way was given up again. Dr. E. Zirm of Olmütz is the first one who has succeeded in carrying to a practical result what formerly was only a theoretical possibility, and has been able to bring about not only perfect repair of a corneal injury, but also the permanent transparency of the graft and consequent restoration of vision. His patient was a man both of whose corneas had been damaged by quicklime and Zirm performed his operation by making use of grafts taken from the eye of a boy that had been removed in consequence of injury by a splinter of iron. In the left eye the power of vision has been greatly improved, so that the patient is able to perform light agricultural work, such as cutting the grass, cleaning the stable, and attending to his cattle; he is also able to go on journeys and find his way about strange places. The graft is visible as a black disk in the midst of the milky surrounding cornea and forms a loophole through which the most minute details of the retina can be inspected with the ophthalmoscope. Zirm attributes his success to the following principles: (1) The use of human cornea, which must be from a youthful individual and well nourished. (2) The use of the trepan and of installations of eserin before the operation if the anterior chamber is still in existence. (3) Profound anesthesia, rigid asepsis, but no antiseptics. (4) The graft is preserved between two bits of gauze wet with sterile salt solution over warm steam until it is to be used; it is then, without the use of instruments, placed in position in the hole bored for its reception. The transplanted flap is kept in its position by two sutures passed through the conjunctiva so as to cross over it.

Three interesting cases of renal affections have been operated on by Illyes; the first was one of hypernephroma. The patient was a man forty-seven years old, who from time to time during the past two years had suffered from bloody urine. It was found that the blood came from the right ureter and on investigating the renal efficiency it was discovered that the right organ had been almost entirely destroyed. At the operation it was seen that the upper pole of the kidney was occupied by a tumor the size of the fist, which turned out to be a malignant hypernephroma. The kidney tissue revealed the lesions of a chronic parenchymatous nephritis. Removal of the growth and the kidney was followed by a recovery. The second case was one of renal calculus; this patient was forty-three years old, and twenty-four years previously a stone had been removed from his bladder. For about two years the urine had been cloudy and colicky pains were complained of on the right side. By means of the cystoscope it was observed that the purulent urine came from the right ureter. A functional examination showed that the organ in question was inefficient, and in a radiograph a faint shadow was visible in the neighborhood of the kidney. At the operation the stone could be felt in the kidney, and after the organ had been removed it was found that its pelvis was distended by a branched stone, while in the calyces other small stones were present. Four weeks later the patient was discharged as cured. The third patient suffered from suppurative nephritis. He was fifty-five years old and for two years had had colicky pains, sometimes on the one side and sometimes on the other. The urine was often bloody, and six months previously two stones were removed from the bladder. Several days before admission the patient had a chill followed by fever. With the cystoscope cloudy urine could be seen coming out of the left ureter and further examination demonstrated that the organ was functionally inefficient. At the operation scattered purulent foci were seen on the surface of the kidney and it was removed. Section of the organ showed that it was filled with numerous small abscesses

from which Friedlander's bacillus was cultivated. The abscesses were of hematogenous origin.

Dr. Stefan Pesthy has carried out observations on the fat splitting powers of the stomach, which have shown that steatolysis in the stomach is not a fermentative process. Digestive tests made with neutralized gastric juice do not show any differences in the extent and amount of fat splitting in normal, hyperchlorhydric, or achlorhydric stomachs. The steatolytic power of the cancerous stomach is extremely slight, however. Pesthy in the course of his investigation examined nearly a hundred stomachs.

A case of echinococcus in an unusual location has been operated on by Polya. The patient was a butcher, twenty-one years old, who had to the right side of the umbilicus a smooth, tense, fluctuating tumor the size of two fists, which moved with respiration and filled the space between the costal arch and the iliac crest. The mass was very movable. The laparotomy incision was made at the outer border of the right rectus, and on opening the abdominal cavity the tumor was recognized as being an echinococcus cyst. It was adherent to the omentum and took its origin from the anterior border of the liver near the gall bladder. At the anterior edge of the liver the cyst was found to have a prolongation the size of a quill, and on following this up another smaller cyst was discovered on the surface of the liver. In order to effect the removal of this cyst it was necessary to resect the ninth and tenth ribs. Recovery was uncomplicated.

A case of severe poisoning with male fern attended by total blindness has recently occurred in Budapest. A young woman suffering from gastric disturbances imagined that she had a tape worm and obtained from a druggist whose advertisement she had read a quantity of capsules of male fern. Following the directions she took nineteen of these in the course of an hour and a half. Severe headaches and abdominal colic followed and some hours later the patient became stuporous. From this condition she did not recover for about thirty-six hours, and then she discovered to her horror that her vision was gone. On examination it was found that the capsules each contained a gram of the extract of male fern, together with a little castor oil. The apothecary was arrested and convicted.

A child with fungous arthritis of the knee and both elbows has been treated with tuberculin of bovine origin by Dr. Hans Salzer. All three joints presented an extreme picture of the disease and discharged fetid pus from numerous sinuses. In addition to treatment by extension of the knee, injections of the tuberculin were given, beginning with a dose of .1 mg. This was cautiously increased to 2 mg. Very marked improvement has resulted, and in consideration of the severity of the lesion Salzer considers the result a very satisfactory one. He is of the opinion that in dealing with surgical tuberculosis in children tuberculin is no more to be dispensed with than is the congestion bandage of Bier.

Progress of Medical Science.

New York Medical Journal, February 23, 1907.

Subinvolution as a Primary Etiological Factor in Gynecological Affections.—J. H. Burtenshaw declares that fully one-half of female pelvic affections are due directly or indirectly to subinvolution of the generative organs. This latter condition arises from too great a blood supply and leaving out infection, this excess is due in turn to either retained secundines or irritation at some point of the genital tract which causes engorgement, more or less chronic. Whenever the uterus fails to undergo the customary involution every organ and tissue physiologically concerned in child-bearing is similarly affected. Laceration of the tissues of the parturient canal is by far the most frequent cause of subinvolution. Long continued congestion ends in hyperplasia. No tear of the perineum or cervix is too insignificant to merit repair. Even if nature heals the open wound the resulting scar tissue may act as an irritant and keep up the congestion indefinitely. Every wounded perineum or pelvic floor should be repaired within twenty-four hours and every wounded cervix within six weeks after confinement. The obstetric specialist does not always see his patients at the end of this period. The patient is often unwilling to submit to examination at this time when she may feel perfectly well in spite of the lack of proper pelvic repair. The author advises against the continuance of the binder after the first few days. The breasts should be regularly emptied. Ergot should be given in diminished doses for several weeks. The bowels should be regularly opened. Hot water douches are of value in promoting involution. If involution is retarded we should search for clots in the uterine cavity and carefully examine the cervix. A dull curette may be used to remove the clots. Finally, if all appreciable causes of subinvolution have been removed and if at the end of ten weeks involution is not complete, a thorough curettage is indicated with the application of pure carbolic acid to the endometrium.

The Trypsin Treatment of Cancer.—J. W. Luther discusses Beard's theories and refers to some of his experiments. He also refers to and summarizes various reports which have appeared on this mode of therapy. He finds a consensus of opinion that the trypsin injections (1) arrest or shrink the growth, (2) improve the general nutrition, increasing appetite, and body weight, (3) diminish or remove pain, and (4) lessen discharge and its fetor except in those cases in which sloughing occurs.

The Fallacy and Inutility of the So-called "Rapid Diagnosis of Rabies."—The conclusions offered by N. G. Keirle are as follows: (1) The presence of the ganglionic changes, described by von Gehuchten and Nelis, or the presence of the structure termed Negri bodies, is not pathognomonic of rabies (hydrophobia), since these are often found when rabies does not exist. (2) The absence of one or both of these appearances does not prove that rabies is absent, since they may be present when rabies is absent and absent when rabies is present; therefore they are not infallible indications of rabies (hydrophobia). (3) In the exigency of treatment, the results of preliminary examinations should not be waited for. When the circumstances are suspicious, when the animal has been killed or has escaped, when a person has reason to think that he has been in contact with the virus of rabies (hydrophobia), he should, as soon as he can, consult his physician, and, preferably through him, should at once communicate with some reputable institution treating this disease preventively, and abide by the advice given.

Live Steam in the Local Treatment of Infection.—F. Griffiths notes the existence of three causative factors in infection after wounds or abrasions, body heat, moisture, and pus germs. To be efficient, heat must be taken as hot as can be borne. The part affected should always be elevated or supported by a sling. Immersion in the hot fluid must be frequent, lasting for from half a minute to five minutes each time. As a rule the less covering of the part the better. The bowels must be kept open by calomel and salines, and some tonic, such as the combinations of iron, quinine, and strychnine, should be given. Rapid drying should follow the immersion in the hot fluid. One of the best methods of applying hot fluid in these cases is the holding of the part against the steam coming from an ordinary tea kettle. Rapid drying will occur within a few moments of each exposure. This method is simple, inexpensive, and always available. The author notes that a jet of steam directed into the uterine cavity has been used as curative in certain disorders of that organ, and it seems clearly practical to the writer to employ live steam projected into the general abdominal cavity through open median incision and repeated, as a means of battling general septic peritonitis, shock as well as sepsis being met by this means.

Journal of the American Medical Association, March 2, 1907.

Herpes Simplex.—J. F. Schamberg holds that herpes simplex and herpes zoster, while not clinically identical, are closely related; the histology of the cutaneous lesions and the observed nerve changes are practically the same in both. Both are due to a variety of causes, but he thinks that the vast majority of all cases are due to the action of a toxin, and this, of course, presupposes an infectious origin. The frequency of herpes simplex in certain diseases and its rarity in others suggest strongly that the toxin must have peculiar qualities to exercise such a selective affinity for sensory nerve structures. He holds, however, that this toxin cannot be the result of the action of any specific organism in the case of herpes simplex, and by analogy not in zoster. The three diseases in which herpes occurs most frequently, and in which it is therefore of diagnostic importance, are pneumonia, spotted fever, and malaria. Schamberg does not commit himself as to its favorable prognostic significance in pneumonia, of which there is considerable evidence, but he does not credit it in spotted fever nor in malaria in this country. The liability of some persons to recurring attacks of herpes must be taken into account in estimating the diagnostic importance of its occurrence.

Unusual Ocular Manifestations of Arteriosclerosis.—The two conditions noticed by Zentmayer are optic atrophy and spasm of the central artery of the retina. The literature and theories of optic atrophy from arteriosclerosis are reviewed and a case reported which seems to him to substantiate the view that with sclerosis of the ophthalmic or internal carotid artery pressing the nerve upward against the unyielding edge of the internal end of the fibrous canal, a transverse pressure atrophy, finally involving the entire diameter of the nerve, may occur. Such a process, he shows, would account for the symptoms and appearances in the case reported. The literature of spasmodic blindness is also reviewed and a case reported in abstract in which the spasm of the ocular vessels was repeatedly observed ophthalmoscopically. It is probably unique in respect, as only three similar cases, but of a single observation of the spasm, were discovered in a search through the literature: those of Wagenmann, Benson, and Sachs, all of which are reproduced in abstract. The patient had arteriosclerosis and probable incipient tabes. The prognosis in these cases varies according to whether the spasm is simply a manifestation of a general spasmodic disorder or of a general grave vascular disturbance. The treatment is that of early arteriosclerosis, high tension, and spasm. Iodid of potassium is the only reliable drug for the arteriosclerosis. Moderation in all things is of more importance than regularity of dosing. The nitrites are available for the spasm, and heart tonics are usually needed. With symptoms of obstruction, massage of the eyeball should be tried. The value of iridectomy is questioned. It may be justified in certain cases, but its efficiency against future attacks is dubious.

Volkman's Ischemic Paralysis and Contracture.—C. A. Powers reports a case of this condition in a boy of seventeen, following a stab wound in the right forearm, and discusses the literature, analyzing the reported cases. The condition is essentially a myositis and is quite different from that following the use of Esmarch's bandage. The characteristic features of both are described. It is usually the result of overtight bandaging in fracture cases, and is most common in children and in the upper extremity. The prognosis is not very good for complete recovery, though a fair result was obtained in a little over half of the cases, and it seems better in patients operated on by tendon lengthening, bone resection, etc., than in others. It begins soon after the use of the splint, with progressively increasing pain, and if the splint is not speedily removed, contractures and paralysis follow. The removal of the cause must be within four or five hours to secure recovery. Primary lesions of the nerves may also exist. The diagnosis is clear, with a history of the case. The English authorities advise massage and passive motion in the slighter cases, continued over a long period if necessary.

Surgery of the Spinal Cord.—The surgical diseases and lesions of the spinal cord are reviewed by J. B. Murphy. He holds that when the axons and ganglion cells that make up the substance of the cord above the cauda are destroyed, regeneration is impossible, and, therefore, in gunshot or stab wounds with immediate paralysis, operation is useless as regards hope of repair, except in the caudal zone, where the possibilities are the same as in the case of wounds of peripheral nerves. Hemorrhage, concussion, and contusion without laceration may give rise to the same immediate symptoms as division, and a positive differential diagnosis is impracticable. The time and order of appearance of symptoms may be the only guides; there is no direct relation between the severity of the trauma and the degree of injury to the cord. Absence of immediate paralytic symptoms is not a guide—they may appear after days or weeks. Early spinal puncture may relieve paralysis due to hemorrhage which in some cases may be as complete as that due to division of the cord. Most patients with incomplete paralysis following fractures recover without operation, and when the displacement is not great the physician is justified in assuming that the cord is not suffering continuous compression and in refraining from operation. The special indications as regards operation in the various conditions above enumerated are pointed out and the technique of laminectomy is described. The danger of delay in conditions calling for operation, especially in non-malignant tumor, tuberculoma, etc., is emphasized. Late operations after necrosis in the cord has taken place are worthless.

Turbinate Hypertrophy.—D. A. Kuyk reviews the objections to the methods of cauterization and excision of the turbinates, and proposes in their stead the making of one or more incisions through the mucous membrane of the hypertrophied turbinate, well down to the bone, when, with a broad nasal saw, the bone is cut to a depth depending on its nature, whether cancellous or vitreous, which is easily detected by the sensation imparted to the hand. If the bone is dense and hypertrophied the cut is carried well down into its substance. Then the nostril is cleansed and the edge of the incised mucosa carefully tucked down into the cut which has been made with a wide saw to allow this. The tissues are kept in place by a carefully adjusted sheet of cotton, saturated with equal parts of compound tincture of benzoin and flexible collodion. This can be left *in situ* for two or three days, when, after careful soaking, it is removed, the tucked-in edges not being disturbed. Repacking is rarely required. The advantages of this method over cauterization or partial or complete turbinectomy are claimed by him to be as follows: 1. Preservation of physiologically active tissues. 2. Freedom from disagreeable reaction or complications. 3. Absence of shock, since but slight local anesthesia is necessary. 4. Freedom from aggravation of existent disease in neighboring cavities. 5. Ease and speed in performance; the instruments used being few and simple.

The Lancet, February 16, 1907.

Operation for Strangulated Congenital Inguinal Hernia Performed on Shipboard Under Difficult Conditions.—The history of this case is detailed by A. B. Francis, who was called to see one of the ship's stewards, about twenty-one years old, suffering from a hernia of the variety indicated in the title. The boy was on his first voyage and had been quite seasick, and the laxness of his tissues, together with the force of his retching, had forced the hernia downward. The size of the swelling was about equal to that of the head of a newly-born child. Hot baths, taxis, morphine injections, chloroform anesthesia were all insufficient to allow of the reduction of the mass. Preparations were made for operation in the ship's hospital and the case came to the table about four hours after the onset of symptoms. The only assistants at hand were some of the under stewards and one hospital steward who had some slight knowledge of drugs, but none in operative procedures. The operator made the usual incision and dissected down carefully. Meantime the captain had slowed down the ship to minimize as far as possible the effect of her motion, and just as the operator was about to enter with his knife the peritoneal sac, the vessel was stopped completely for a few minutes. The operation was successful and the man made an uneventful recovery.

Reunion of an Almost Severed Leg.—T. Hayes reports the case of a lad of eighteen years who was run over by a mowing machine. The tendo Achillis, the tibia, and the fibula were completely cut through, the only parts escaping amputation being the tendons and other tissues in front of the bones. The boy was placed in a cart and started for the doctor's office twelve miles away. On the journey it was feared that he would bleed to death, and a stop was made at a town where a young army surgeon was found who advised immediate amputation. This was refused by the mother, who accompanied the boy, and finally the author was sent for. He reached the patient about twenty-four hours after the injury and found the almost severed limb turned up to the shin, a large plug of lint in the wound, and all well bandaged. Examination showed that the anterior tibial vessels were still carrying on the circulation, as the foot was warm. The parts were cleansed, the ends of the tendo Achillis brought together with some very strong sutures, and a lint and water dressing applied. The author also put on a slipper with a strap attached and fixed to the knee to extend the foot backwards, bent the foot backwards, and kept the knee also bent. The case did well. At the end of a year the man was able to walk without limping, but with a stiff ankle joint. Thirty-five years later the patient walked without any apparent lameness. There was a slight projection of the inner ankle and a sulcus over the cicatrix.

Value of Bacteriological Examinations of the Blood in Typhoid Fever and other Bacteriemias.—F. G. Bushness notes that in his district (Brighton) the Widal reaction for typhoid frequently gives indefinite reactions, such as slight loss of motility of the bacilli, and a few small loose clumps within one hour, even when the clinical diagnosis is typhoid fever, and this may be so even in the third week of the illness. The absence of agglutination may be due either (1) to defective formation of agglutinins or (2) to the infection being

due to a bacillus which, though closely allied to, has specific differences from, the bacillus used to carry out the serum reaction; for example, paratyphoid infection would fail to agglutinate "completely" cultures of the bacillus typhi. He believes that the value of the agglutination test by a minimum serum in establishing the identity of the bacillus in question cannot be overestimated. The cultural tests under those circumstances are, in his experience, comparatively valueless, being mostly negative. Details of one case are given, illustrating the author's contentions.

British Medical Journal, February 16, 1907.

Deafness in Myxedema.—The patient whose history is reported by W. R. Kemp was a woman of fifty-five years, presenting the usual features of myxedema, though her only complaint was of deafness. When she did hear, questions were not answered at once, there being some few seconds spent in hesitation before a sentence was commenced. She spoke in a dull, apathetic tone, and had considerable difficulty in articulating long words. She was placed on a light, nutritious diet, with laxatives at bed-time as required, thyroid extract in tabloids of gr. ijss being given three times a day after each meal during the first fourteen days, after which the dose was doubled. After six weeks some signs of recovery appeared, the swelling of the body decreased, and the hearing and speech improved considerably. The point which seems to make the case worth reporting is the deafness, which may have been due to the thickness and dryness of both tympanitic membranes. The author has not found any reference to deafness as a feature of myxedema in the text-books or current literature.

Typhoid Fever Simulating Cerebrospinal Meningitis.—J. A. Cowie's case was that of a coal miner, seen two weeks after his initial symptoms and considered as a case of cerebrospinal meningitis, his symptoms being almost typical of this malady. Lumbar puncture was done, but no fluid obtained. The agglutination test was negative and the *Diplococcus intracellularis meningitidis* could not be isolated from the blood. The patient died on about the sixteenth day of his disease, and autopsy revealed the abdominal lesions of typhoid. The brain membranes were in a state of extreme congestion, and pus was seen on the surface of the brain in the temporal region. At the base of the brain a seropurulent fluid was found in large quantity, and a specimen of this under the microscope showed pus cells and a number of diplococci, and also diplococci in rows. Examination of a specimen of the cerebrospinal fluid showed that neither the *Bacillus typhosus* nor the *Diplococcus intracellularis meningitidis* were present, but a Gram-positive diplococcus occurring in chains was isolated. Two c.c. of a broth culture of this diplococcus were injected intravenously into a rabbit, but as the animal was quite well after two days the diplococcus was proved to be nonvirulent.

The Treatment of Rodent Ulcer by Zinc Ions.—H. L. Jones says that the apparatus required for this therapy is simple. An ordinary medical continuous current battery, with a galvanometer, a pair of wires, a flat pad for completing the circuit at the negative pole, and a rod or other electrode of zinc attached to the positive pole, completes the outfit. The zinc must be covered with three or four layers of lint, which serve as a reservoir to hold the zinc solution, a two per cent. solution of the sulphate being very suitable. The zinc should be freshly cleaned or amalgamated, and the solution should be made with distilled water. It is as well not to touch the zinc electrode or its covers with the fingers unnecessarily, because every touch imparts a trace of sodium chloride from the skin, and tends to reduce the efficiency of the process a little by bringing in some foreign ions. The circuit is completed through the usual pad electrode applied to any convenient part of the patient, the zinc electrode of suitable size is held upon the rodent ulcer, and the current is slowly turned on until a current of five, or eight, or ten milliampères is reached, according to the size of the electrode used. Ledue has advised that a suitable magnitude of current to use is two or three milliampères of current for each square centimeter of the positive electrode, and, in general, patients can bear this concentration of current without complaining. The sensation produced is a burning one, not unlike that of a mustard plaster. In patients who are sensitive it may be convenient to introduce a little cocaine beforehand. When the surface is raw the cocaine solution can be directly applied on a tuft of cotton-wool left in contact with the ulcer for a few minutes. When there is no raw surface the drug can be helped to penetrate electrolytically from the positive pole if, before using the zinc solution, a tuft of wool moistened with cocaine solution is applied to the surface of the rodent ulcer, and the current passed in with the zinc electrode, exactly as for the introduction of the zinc. The preliminary use of cocaine permits of the use of a somewhat stronger current. It is necessary to use a pure solution of cocaine, and not a solution containing sodium chloride or any other salt. Occasionally the condition of the ulcerated surface offers some difficulties to the even distribution of the zinc ions. Occasionally, also, it may be necessary to puncture certain areas with the zinc needle if the application of a flat electrode is not practicable. Other cases which are difficult are those which have been operated upon by *x*-rays or by the knife, and have relapsed, for they have a tendency to recur at several points around the original site, and also to invade the subcutaneous tissue. If they have a thickness greater than two or three millimeters, it is difficult, in a reasonable time, to drive the zinc ions inwards to a sufficient depth to influence the deeper parts, unless a zinc needle is used. The advantage of using a needle is that time is saved, for if one can push the zinc needle into the depth of the part to be destroyed, the migration of the ions into the surrounding layers is accelerated, and this is a great advantage, because the rate of movement of the zinc ions is slow.

Ichthyosis and Its Treatment.—W. A. Jamieson gives the histories of several cases illustrative of the varying phases of this affection. He declares that our therapeutic efforts should be directed toward the promotion of the regular systematic exfoliation of the unduly adherent and effete horny cells. There are various substances which have the power of thinning down, artificially, the epidermis. Sulphur is one, but if used it not only adds to the abnormal aridity, but is apt to set up exudative and even inflammatory processes. Salicylic acid, too, in the dilute form in which alone it can be prudently employed over extensive areas and for a length of time, fails to accomplish what is needed. Resorcin, however, not only favors continual desquamation, but tends to leave the subjacent surface polished and pliant; hence its use is specially indicated. Combined with an oily base it dries up or is rubbed off. Glycerine from its hygroscopic properties is the excipient *par excellence*, but applied alone is rather irritating. In union with starch it forms a bland, persistent, soothing, and softening medium, and, as has been seen, while in all cases so used it proves eminently beneficial, if its application is begun early enough and steadily persevered in, it can effect what must be regarded as a cure. At the same time, with all its qualifications, the resorcinized glycerite of starch alone would not enable us to get continuously rid of the ever newly-forming accretions of epidermis. We must therefore have recourse to a medicated soap, and a superfatted one with which resorcin and salicylic acid are incorporated—that which is so valuable in shortening the desquamative stage in scarlet fever—has proved adequate, and prepares the way for the subsequent glycerinization. Internal remedies are of little use in ichthyosis. The only one which aids us at all is cod-liver oil administered in small doses at night. Pilocarpine is inoperative in early treatment, unnecessary in later.

Berliner klinische Wochenschrift, February 11, 1907.

The Sphygmoscope.—Rheinboldt gives this name to an instrument he has devised primarily for the purpose of facilitating the use of the sphygmomanometer. It is intended to render the determination of the point at which the pulse wave becomes obliterated susceptible of objective demonstration. In order to effect this the patient's index finger is inserted into a suitable adjustable collar supported on a tripod and connected with a double lever by which the alteration in the size of the member with each pulse beat is manifested by a considerable excursion of the indicator. It was found that readings of the sphygmomanometer made by means of the instrument were somewhat lower than those in which systolic pressure was determined by the sense of touch, but the difference is a consistent one and the author considers that it does not invalidate the appliance. He has also found it very useful as a means of obtaining information in regard to the regularity of the heart action and of detecting variations in rate and intensity of pulsation that otherwise might easily be overlooked. Advantages of the instrument are its simplicity compared with the sphygmograph and its consequent ease of adjustment and cheapness.

Münchener medizinische Wochenschrift, January 29, 1906, and *February* 5, 1907

Nervous Disturbances Accompanying Digestion.—Kehrer calls attention to the frequency with which unpleasant dreams, and more particularly the classical nightmare, occur during the early hours of sleep when digestion, in accordance with the German custom of taking the evening meal at about eight o'clock, is still actively going on. He considers that during the period in which the gastric contents are being expelled into the duodenum,

nervous disturbances of the future are particularly likely to be induced, and suggests that this may be the result of the sudden flooding of the circulation with the products of digestion which may result in evoking these evidences of stimulation in the brain. Persons who are subject to disturbances of this sort should allow three or four hours to elapse between the last meal and going to bed; should not let this last meal be too hearty a one, and should make it a point to avoid all indigestible dishes and alcoholic drinks with the evening meal.

The Use of Rubber Gloves.—Walther in discussing this subject admits that by the use of rubber gloves it is possible for the surgeon to operate with perfectly sterile hands, but he considers that in spite of the statements made by many surgeons, even long habituation to their use does not compensate for the impairment of tactile sense the gloves entail. Particularly in such obstetrical manipulations as removal of the retained placenta or in cleaning out the uterus after an incomplete abortion is it desirable that the operator shall have full possession of the utmost degree of tactile sensibility, and under these conditions the use of gloves may be a source of danger rather than of safety. It is his attitude that the gloves should be used rather for the purpose of protecting the physician's hands from contamination in making rectal examinations, handling infectious material, etc., than as a routine in operative surgery and gynecology. In regard to a proposal recently made to have the use of gloves made obligatory for country midwives, Walther expresses his unqualified disapproval of such a measure. It is necessary, if gloves are to be used, that both the hands and the gloves be sterilized with all possible care, and if the gloves are made compulsory, the average midwife is sure to relax her precautions in the one respect or the other. The introduction of the glove would form a needless addition to the appliances to be kept in order by the midwife and would be found an unnecessary, expensive, and dangerous innovation.

The Treatment of Tetanus.—Glänzel makes the successful outcome of a severe case of tetanus the text for a discussion of the antitoxin treatment of the disease. The patient was a young man of eighteen years, and the treatment carried out comprised the customary administration of chloral, morphine, and potassium bromide in large quantities, as well as the use of antitoxin. An unusually large amount of this was injected, and it is the author's aim principally to call attention to the necessity for resorting to much larger doses of the antitoxin than are usually given. He believes that it has been demonstrated that the toxin is disseminated through the body by way of the blood stream, and not through the nerves, as was formerly supposed, and therefore the subdural injection of antitoxin is not necessary. The local treatment of the site of infection is exceedingly important, and should be carried out in as radical a manner as possible without causing undue mutilation, but the early and repeated administration by hypodermatic injection of large amounts of antitoxin should never be neglected. Prolonged warm baths are also mentioned as a valuable adjunct to the treatment.

Operations on the Hands.—Vogel suggests that in order to secure more effective sterilization before performing operations on the hands, particularly plastic procedures the patient be directed for two or three days preceding the operation to place the hand for one hour, night and morning, in a hot-air apparatus of the type devised by Bier. By this means very profuse perspiration is induced and relative asepsis can be much more easily secured. This is particularly true in dealing with the hands of mechanics or laboring men whose skin is apt to be very thick and grimy. Another advantage of the plan is to be that the occurrence of small areas of necrosis along the line of suture that so frequently takes place in operations of this sort seems to be obviated.

Deutsche medizinische Wochenschrift, January 3, 17, and 31, 1906, and February 7, 1907.

Removal of a Foreign Body Through the Bronchoscope.—Winckler says that it is no longer permissible in dealing with a patient supposed to have aspirated a foreign body to pursue an expectant plan of treatment in the hope that in the course of time the intruding substance will be coughed up. The *x*-ray is unreliable as a means of locating small bodies in the bronchi, and the bronchoscope now forms the most satisfactory diagnostic and therapeutic instrument. A patient whose bronchi contain a foreign body must be regarded as a seriously sick person, even if there is but little disturbance in general health, and in case there is any suspicion of the aspiration of a foreign body bronchoscopy should be resorted to without delay. Winckler describes a case of his own in which a woman of fifty-eight years inadvertently drew into her lungs a fragment of bone. Cough with putrid purulent expectoration ensued and two months later, when she came under the author's observation, the expectoration was extremely fetid. By means of a rather complicated application of the bronchoscope, it was finally possible to remove two spicules of bone from a portion of the right bronchus, thirty-four cm. from the lips. One of the fragments measured 13 by 7 by 1 mm., and the other 9 by 2 by 1 mm. The fetor of the expectoration promptly disappeared, though the other evidences of bronchial and pulmonary irritation were slower in subsiding. Ultimately complete recovery in every way occurred.

The Reflexes During Sleep.—Kutner has tested the reflexes during sleep in a considerable number of patients suffering from nervous diseases. He believes that the opinion expressed by many observers that the deep tendon reflexes are absent during sleep is erroneous and is dependent largely on the difficulty of eliciting such reflexes without waking the patient. He tested the knee jerk in twelve cases, and the achilles tendon reflex in twenty-two cases. The patellar reflex was present in all the patients, but in three instances the achilles tendon reflex could not be elicited. It was found, however, that in these patients even when awake this reflex could not be obtained when the limbs were placed in the position they occupied during sleep. The superficial reflexes are easier to test during sleep, and the various plantar reflexes, the only ones tested, were found to be normal in the sleeping patients. The great toe reflex formed an exception, however, and variations could be distinguished according to the nature of the patient's malady. In cases of progressive paralysis and delirium tremens a positive Babinski reaction was found in from a half to two-thirds of the cases, whereas in psychoses of a different nature the reflex was absent. The author points out that in the first two conditions there are organic changes in the brain and that the association with these of the Babinski phenomenon during sleep is very suggestive in view of the fact that in the waking state the reflex ordinarily indicates a lesion of the pyramidal tracts.

Fever in Carcinoma.—Alexander gives the histories of a number of cases in which malignant new growths were accompanied by more or less persistent and well-marked fever. These observations, as well as a review of the literature, lead him to the conclusion that there is a definite cancer fever which is independent of complications. This febrile movement may follow various types, and is not bound to any definite form. It occurs as the result of autointoxication resulting from absorption of products formed through the metabolic activities of the new growth itself. In most cases of febrile cancer the new growth is situated in the abdominal cavity, and is particularly apt to involve the alimentary tract. While it might appear that in ulcerating growths the conditions were particularly favorable for the occurrence of temperature elevations, this is not so, and clinical experience shows that in such cases the appearance of fever has no direct relation to this characteristic of the tumor.

Complications Caused by the Therapeutic Application of the Roentgen Rays.—Engel has compiled a long list of the various more serious complications that have been reported as attending the use of the Roentgen rays for therapeutic purposes and calls particular attention to a form of toxemia that is sometimes observed. In a case of his own a patient of fifty-four years suffering from lymphatic leukemia in the course of a series of *x*-ray treatments developed high fever, collapse, diarrhea, rapid loss of strength, and heart failure, finally leading to death under the appearance of an intense toxemia. Inasmuch as the leukemia had been of a pronouncedly chronic type, it seems certain that the rapid course of the illness must have been the result of the *x*-ray radiation, a view that is strengthened by the rapid reduction in the number of red and white blood cells and in the size of the spleen and lymph glands that ensued. In this case the total length of exposure was 350 minutes in eleven days, and although the total number of *x*-ray minutes was not very large it seems not unlikely that the treatments were given at too short intervals. The author suggests that no *x*-ray treatment should last more than two minutes at a time, with the tube at a distance of 20 cm. or four minutes at a distance of 35 cm.; the same portion of the body should not be treated more than two or three times daily, and very hard tubes should be used for therapeutic purposes. The portions of the body surrounding the area to be treated should be protected with lead plates, and after every five or six treatments a rest of a week or so should be allowed.

The Axillary Regions are recommended by Klose as being the best situation in which to inject antitoxin or similar preparations, as the skin is freely movable, is well padded with fat and connective tissue, and the lymphatics are well developed.—*Deutsche medizinische Wochenschrift.*

Book Reviews.

THE PRACTICE OF OBSTETRICS, in Original Contributions by American Authors. Edited by REUBEN PETERSON, M.D., Professor of Obstetrics and Gynecology in the University of Michigan, Ann Arbor, Mich. Obstetrician and Gynecologist-in-Chief to the University of Michigan Hospital. Philadelphia and New York: Lea Brothers & Co., 1907.

THIS is the third of the series of books in "The Practitioner's Library," the other two being on Pediatrics, edited by Dr. Walter Lester Carr, and Gynecology, edited by Dr. J. Wesley Bovée. These two have already been reviewed in our columns, and we cannot say more for the present volume than that it is the equal, in all essentials, to the others of the series. The contributors to this volume are Drs. Charles Sumner Bacon and Henry Foster Lewis of Chicago, Montgomery A. Crockett of Pinehurst, N. C., W. A. Newman Dorland of Philadelphia, G. Carl Huber and Alfred Scott Warthin of Ann Arbor, Mich., Hugo Ehrenfest of St. Louis, Walter P. Manton of Detroit, John F. Moran of Washington, and Benjamin R. Schenck of Baltimore. The sections into which the work is divided are on Physiology and Development of the Ovum, Physiology of Pregnancy, of Labor, and of the Puerperium, Pathology of Pregnancy, of Labor, and of the Puerperium, Obstetric Operations, and the Newborn Infant. The book is profusely illustrated, more perhaps than is expedient, for some of the subjects do not require such elaborate illustration, and the pictures take up much room and increase unduly the size and the weight of the book. The illustrations are, however, excellently done and very distinctly printed, and most, at least many, of them are clearly original. There are 523 illustrations in the text and thirty full-page plates. The articles are not all of the same standard of excellence, but as a whole there is little criticism to be made of the work as a trustworthy guide to the obstetric art, and we can safely recommend it to the student or practitioner who wishes for an up-to-date text-book on this subject.

A GUIDE TO DISEASES OF THE NOSE AND THROAT AND THEIR TREATMENT. By CHARLES A. PARKER, F.R.C.S. Edin., Surgeon to the Golden Square Throat Hospital, London, with 255 Illustrations. New York: Longmans, Green & Co.; London: Edward Arnold, 1906.

BOOKS on nose and throat diseases are following each other from the press in such rapid succession that a review becomes difficult, inasmuch as they all cover practically the same ground, and the differences between their various statements refer to minor points which are of interest only to the specialist. Dr. Parker incorporates in this volume his lectures given at the well-known London institution, and his method of putting things is well expressed in his own words in the preface, to the effect that the three most important objects of a course of study at a special hospital are "to acquire the necessary dexterity to examine a patient systematically, so as to overlook nothing, to recognize and put in its proper place the particular pathological condition found, and finally, but chiefly, to treat both the patient and the local abnormality successfully." As suggestive of his adherence to these principles is the fact that he puts his chapter on "Complications of the Upper Respiratory Tract in relation to General Medicine" *before* instead of *after* the detailed maladies of the nose, nasopharynx, and throat. By this we understand that the author realizes that rhinology and laryngology are but parts of medical science, and by no means the whole of it. The book is well printed, the illustrations are clear, the index is excellent, and this record of a vast clinical experience is worthy of perusal by all interested in this field of professional work.

THE MEDICAL EPITOME SERIES: PATHOLOGY, GENERAL AND SPECIAL. A Manual for Students and Practitioners. By JOHN STENHOUSE, M.A., B.Sc. Edin., M.B. Tor.; and JOHN FERGUSON, M.A., M.D. Tor. Illustrated with 16 Engravings and a Colored Plate. Philadelphia and New York: Lea Brothers & Co., 1906.

THE first half of this book is devoted to general pathology, and treats of the various topics usually included under this head. The subject of inflammation is disposed of in some half dozen pages. The classification of tumors adopted is the recent one of Adami, which, while possibly scientific, is likely, with its novel nomenclature, to add to the difficulties of the student; to the practitioner it will probably be less intelligible than the one he learned at college. Two useful chapters are those on toxemia and immunity. The second half of the book deals with special pathology, and calls for no special comment. The volume, as a whole, is of about the same standard as the rest of the series.

GREEN'S ENCYCLOPEDIA AND DICTIONARY OF MEDICINE AND SURGERY. Vol. II. Bread to Ear. Edinburgh and London: William Green & Son, 1906.

THIS is the second volume of this very complete and useful work. It carries the subject matter along to and including "Ear." There are 1,758 separate headings, the articles under each varying from the few words needful as a definition to an encyclopedic article of more than 1,000 words in length. The dictionary part of the work is a very valuable feature, including most of the titles which would be looked for in any ordinary medical dictionary. In the present volume, for instance, under the head "Disease" are defined nearly one hundred eponymic terms. The intrusion of the names of clinicians and others in the designation of special diseases is a great evil in medical nomenclature, but since it has occurred and careless writers use such terms continually, a definition is often very necessary. The editor has met the trouble in the best way, and with the greatest economy of space, by grouping all these eponymic terms under the one title. There are not many illustrations, but such as there are are judiciously chosen and are helpful. This second volume sustains the character of the work as one of great utility to the practitioner of medicine.

A TREATISE ON THE MOTOR APPARATUS OF THE EYES, Embracing an Exposition of the Anomalies of the Ocular Adjustments and Their Treatment, with the Anatomy and Physiology of the Muscles and Their Accessories. By GEORGE T. STEVENS, M.D., Ph.D. Philadelphia: F. A. Davis Co., 1906.

THE work, as stated by the author in the preface, is a sequel to that on "Functional Nervous Diseases," and is presented as a further argument to support the central idea, namely, that "difficulties of adjustment of the eyes are a source of nervous trouble and more frequently than other conditions constitute a neuropathic tendency." The book is one of 496 pages, well printed and illustrated. The text proper is divided into four parts, and the different topics are considered in sections. The introduction is an historical sketch and gives the views of Stromeyer, Dieffenbach, von Graefe and others on strabismus, and of von Graefe, Soelberg-Wells, Galezowski, Landolt, and others on heterophoria or "insufficiency of the internal recti muscles."

Part I. treats of the anatomy of the motor muscles of the eyes, and of the parts accessory to them. The comparative anatomy of the eye muscles of fishes, reptiles, birds, and mammals is described and illustrated. The bony structure, size, and position of the orbits in man are carefully described. A study of the plane of the orbital axes in relation to the horizontal plane of the cranium, with a view to its bearing on the visual plane, is here set forth. In the sections treating of the contents of the orbit, the insertion of the extrinsic eye muscles into the globe and the relation of Tenon's capsule to the globe, eye muscles, and orbit are considered in detail.

Part II. is devoted to physiology. The laws of torsion, field of binocular vision, the horopter, the normal direction of the planes of vision in relation to certain cranial characteristics and stereoscopic vision are described and discussed.

Part III. treats of "anomalous conditions of the motor muscles of the eyes consistent with the physiological state." An explanation of the terms introduced by the author is given. In this part are found descriptions of the use of the tropometer, of the clinoscope, of the phorometer, and the Maddox rod. A discussion of torsion or declination of retinal images, also of the various departures from the normal in the direction of the visual lines, the uses of prisms, causes of strabismus, etc., are included.

Part IV. treats of "anomalous conditions of the motor apparatus of the eyes not consistent with the physiological state." To these conditions the term "colytropia" is applied. This parts treats of spasm, of paralysis, and of obstruction to the action of the "motor" muscles of the eyes.

The volume presents the views of one well fitted in every way for the work, who has devoted many years to the theoretical and clinical study of the subject. Much that it contains is original with the author. Many of the views expressed have been previously published, but they are here collected and systematically arranged, making a complete whole. No one who is studying ophthalmology, or who is engaged in the practice of ophthalmology, can afford to neglect to acquaint himself with the contents of this volume. In many respects it marks a distinct advance in our knowledge of some of the subjects of which it treats.

STUDIES IN THE PSYCHOLOGY OF SEX. Erotic Symbolism; The Mechanism of Detumescence; The Psychic State in Pregnancy. By HAVELOCK ELLIS. Philadelphia: F. A. Davis Co., 1906.

WITH the appearance of this volume, the fifth of the author's stories of sexual phenomena, the series draws to a close. The next and last volume, he states, is to be devoted to a consideration of the bearings of the psychology of sex to social problems in general. The first section of the present work includes a résumé of the sexual perversions and aberrations, the second is devoted to an analysis of all the phases of the culmination of the various psychical and physical phenomena for which the period of tumescence has furnished the preparation, and the third deals with the emotions attending the pregnant state.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON SURGERY.

Stated Meeting, Held January 4, 1907.

DR. JOHN F. ERDMANN IN THE CHAIR.

A Case of Synovitis of the Sacroiliac Articulation.—Dr. HENRY W. FRAUENTHAL presented this case, a boy, 11 years old, who, on June 26, 1906, was struck by a cable car. He was in the hospital for some time, and discharged as cured of his injuries. At present he had synovitis of the right sacroiliac articulation. He could raise his left leg with the knee fixed. He could not raise the right leg when the knee was fixed, and, on attempting to do so, complained of great pain at the sacroiliac joint, when the knee was flexed on the pelvis. The motions of the right and left hip joints were equal. Pressing the pelvis together produced pain at the articulation of the right sacroiliac joint. Making pressure on the erector spinæ muscles and on the latissimus dorsi on the right side produced pain at the sacroiliac joint. Pressure on the same muscles on the left side elicited no pain. The patient in walking leaned to the right side. He had a peculiar gait due to the contractions of the ham-string muscles on the right side.

Traumatic Amputation of Finger; Autoplasty.—Dr. HERMAN C. FRAUENTHAL presented a man who, in the summer of 1903, while cleaning the chain of a bicycle, turned the wheel with his left hand and caused the index finger of the right hand to be caught between the sprocket wheel and chain, amputating the soft parts of the finger at the second phalanx. He came to the office with the first and part of the second phalanges stripped of the soft parts, exposing the bones and first joint. Dr. Frauenthal sent him back to the stable, about a mile away, for the thimble-shaped soft parts. After soaking them in hot saline solution, they were replaced with zinc oxide plaster and balsam of Peru, and healing took place kindly. The head of the first phalanx eventually necrosed and came away. The absence of the head of the first phalanx could be seen in the radiograph. Sensation was just returning to the part of the finger injured, though incompletely as yet.

Motor-Boat Fractures.—Dr. HENRY P. DEFOREST presented this paper and illustrated it with *x*-ray photographs. He said that in most instances the machinery of a boat, usually with gasoline as a motive power, was started by hand. The more or less heavy balance wheel of the engine had a permanent handle projecting from the rim, or a heavy brass or iron rod sunken in a socket and held in place with a spiral spring when not in actual use. When the engine was started this handle was seized and the wheel turned quickly around. Occasionally something happened and the engine started, oftentimes with great rapidity. The handle might escape from the grasp, might fly around, and strike one on the hand before the hand had a chance to get out of the way. The injuries resulting from this impact were usually trifling, but the speaker cited several cases to show that some of them might be very serious. Similar injuries occurred during the "cranking" of an automobile. The fact that the initial velocity of the flying handle was much greater than that of the human body, in a case of a fall, or that of falling timbers, stones, and the ordinary causes of fracture in every-day life, had a marked effect upon the lines of fracture, and caused them to resemble those produced by large caliber projectiles without the penetrating effects. The fracture, as a rule, was rarely transmitted to the weaker parts of the bone. So localized was the injury that fragments of bone might be broken off, or such small bones as those of the carpus might be individually broken. As a rule, the line of fracture was straight and the direction taken quite unusual. Diagnosis was often difficult. The dangers were now becoming known, and schools of instruction in the complete construction and management of motor boats were now established.

Duodenal Fistula; Its Treatment by Gastrojejunostomy and Pyloric Occlusion.—Dr. A. A. BERG read this paper. A duodenal fistula, unless it was of pin-hole size, usually occasioned a very rapid death from starvation. The duration of life after the establishment of such a fistula depended upon the size of the opening into the duodenum and upon the readiness with which the duodenal contents were discharged. All the numerous mechanical devices for the relief of this condition had proved inefficient. With the view of preventing the rapid deterioration of patients afflicted with duodenal fistula, Dr. Berg proposed (*Centralblatt für Chirurgie*, 1903) that a gastroenterostomy be established and the pylorus occluded. The proposition at that time had not been tested in actual practice, but since then he twice had had occasion to carry it out, and it was his wish to report on its efficacy in overcoming the otherwise fatal lesion and to suggest some points of practical importance in the technique of its performance. In the first case he reported it was evident that impending death was averted from duodenal leakage by the gastrojejunostomy and pyloric occlusion. The ultimate fatal issue was not due to the complicating duodenal leakage, but to cancerous cachexia. In reviewing the details of the operation, two important points came up for consideration. First, was it necessary in order to divert the chyme from the duodenum into the jejunum to occlude the pylorus, or was it sufficient to simply make a gastrojejunostomy. Second, if it was essential to occlude the pylorus, then great care must be exercised in applying the occluding ligature, lest it cut through the tissues. Regarding the first point, he said it was commonly believed that if a gastrojejunal fistula was established at the lower point of the stomach, the gastric contents would be emptied directly into the jejunum through this anastomotic opening, even when the pyloric opening in the stomach was patent. This was, however, an erroneous belief. Kelling's experiments upon dogs, and his own clinical observation, conclusively proved that when the pylorus was patent a gastrojejunostomy would not divert the chyme from the duodenum into the jejunum. Consequently, when they had to do with a duodenal fistula, it was necessary, not only to establish a gastrojejunostomy, but also to occlude the pylorus. With regard to the second point, however applicable Kelling's method was when they had to deal with normal serous coverings of the stomach and duodenum, it was not applicable when the peritoneal surfaces of these viscera had become brittle and friable, and fixed in inflammatory exudate. In such conditions, in order to occlude the pylorus, one must resort to a circular ligature. In the application of this ligature the greatest care must be exercised not to constrict the parts, for otherwise this ligature would be cut through the pylorus. This tendency to cut through was all the more prominent because of the usually poor vitality of such tissues. In cases of ruptured duodenum that might be followed by a fistulous opening, was it advisable to resort to a primary gastrojejunostomy and pyloric occlusion in addition to repairing the opening in the duodenum, or should they content themselves at the first operation with direct repair of the perforated viscus? In answer to this, Dr. Berg said that if the peritoneal surfaces surrounding the perforated part were normal, not brittle or friable, or fixed in inflammatory exudate, they had every reason to expect a successful issue by suture. But, if such was not the case, it was not likely that the healing by suture would occur, and, in such cases, it would be wiser at once to proceed to a gastrojejunostomy and pyloric occlusion. Again, if by the sutures they constricted the lumen of the duodenum sufficiently to interfere with the transmission through it of the chyme, it was likewise best to at once proceed to gastrojejunostomy and pyloric occlusion. But, if a primary gastrojejunostomy and pyloric occlusion had not been done, one should at

once perform them when the suture of the duodenal opening proved itself insufficient. Repeated attempts at repair of the viscus suture would almost invariably result in failure to effect its occlusion, and would be followed by death.

Dr. Charles H. Peck said that in all the cases of duodenal fistula he had seen the surrounding walls had been friable, rendering suturing uncertain. He had been fortunate in not encountering leakage afterwards. He did not believe that in all cases where this infiltration existed they would fail to get healing of the ulcer. He was accustomed to first place a large purse-string suture at some distance from the perforation before applying the Lembert sutures. There was no doubt but that the friability of the tissues caused the sutures to cut through. It seemed to him that in the acute cases of perforation, the cases in desperate condition, with leakage and a general peritonitis, that the performance of a gastrojejunostomy was dangerous and increased the mortality; he said he would be inclined to make an attempt to terminate the operation as soon as possible with a single suture.

Dr. Charles A. Elsberg had had only one case of ruptured duodenal ulcer, and he recognized the rationality of Dr. Berg's suggestion. He exposed the surface of the stomach and the ulcer, which was situated at the junction of the second and third portion of the duodenum, and he sewed the surface of the stomach over the ulcer, and with satisfactory results. The patient did well and made an entire recovery. He said he was struck at the time with the idea, whether it was not possible and feasible in cases of perforated duodenal ulcer to at once do a gastroduodenostomy. If the perforation was high up, he thought Dr. Berg's method a rational one, but with this exception; if the perforation was below the site of the entrance of the common bile and pancreatic duct, there would still be a continual leakage of bile and pancreatic fluid, and so be a decided factor in preventing the recovery of the patient.

Dr. Samuel Lloyd agreed with Dr. Berg that it was impossible to divert the stream from the pyloric end of the stomach in such cases by doing a gastrojejunostomy alone. If the object was simply to cause a rest of the part, gastrojejunostomy would not be efficient unless some method was adopted for closing the pyloric end. He did not agree, however, that a gastrojejunostomy should be made first, and before the duodenal fistula was closed; an attempt should be made to close the duodenal fistula. These cases would stand much operative manipulation. The dangers of peritonitis were not so great when operating in the upper part of the peritoneal cavity as in the lower part. Consequently, Dr. Lloyd attacked these cases more actively than if the fistula involved the lower portion of the peritoneum. Dr. Peck's suggestion of using a purse-string suture and then the Lembert's suture appeared to him as feasible. Dr. Elsberg's suggestion also appealed to him strongly. He recently had a case of duodenal ulcer with the ulcer extending from the pylorus into the duodenum. There were multiple ulcers, one of the pylorus and two good-sized ulcers on the anterior wall of the duodenum. In this case he carried out the suggestion of Dr. Elsberg, making a complete removal of the pylorus and brought up the duodenum into the wound, and with a perfect recovery. The fistula should first be closed if possible; if they failed, then they should proceed with the closure of the pylorus.

Dr. Berg believed that he had had seven cases of rupture of the stomach and duodenum to deal with; in five of these he effected a primary closure, knowing the suture line would remain intact. In two he was not able to effect this. He thought that in a large majority of these cases one could be able to tell, with a fair amount of certainty, whether or not the attempt to close the ulcer by suture would be successful. When the perforation was situated high up, the suture method was more likely to be successful, even though there was a considerable inflammatory exudate. If, however, the same inflammatory mass existed at the pyloric region, giving less room for bringing the parts together, attempts with suturing were likely to be less efficacious. He had absolutely no reason to propose primary gastrojejunostomy with pyloric occlusion in any case where the surgeon felt that the suture line would be a tight one, but where the surgeon felt that the suture would not be successful, the question of primary gastrojejunostomy with occlusion of the pyloric end should come up. With regard to the length of time that a patient would live after leakage, that depended upon the size of the hole in the duodenum. This question of primary gastrojejunostomy depended upon the character of the tissues surrounding the ulcer. If the indurated area was some distance around the perforation, this operation could not be trusted. Murphy's button was out of the question. The suture operation held out such a slight chance for success that the procedure should not be considered under such circumstances.

Stated Meeting, Held February 1, 1907.

Dr. John F. Erdmann in the Chair.

Plastic Repair After Removal of Carcinoma of the Cheek and Left Angle of Mouth.—Dr. Franz Torek presented this patient. An excision had been done by another surgeon, but the growth had recurred and carcinomatous glands had developed in the submaxillary region. Dr. Torek first extirpated the lymphatic glands by an incision from the chin to the hyoid bone, thence outwards along the boundary line between the floor of the mouth and neck, thence upward to a point behind the angle of the jaw. The flap was prepared upward and all the glands were cleared out. He next excised nearly the whole cheek and part of the upper and lower lips. The divided ends of the lips were united, leaving a large hole in place of the cheek. Remnants of mucous membrane of the cheek could not be approximated. As failure to replace the mucous membrane would result in cicatricial contraction and subsequent impossibility to open the mouth, a plastic operation had to be performed. Last year Dr. Torek presented a patient in whose case he had used the skin of the neck to replace the mucous membrane. In this case he took a long flap from the tongue with its pedicle at the root of the tongue, twisted it so that the raw side looked outward and the mucous membrane side inward, and he attached this to the margin of the mucous membrane of the cheek. The skin defect was closed by utilizing the flap which had been raised from the submaxillary region for the purpose of extirpating the glands. The skin was undermined still further upward into the open cut, thus making a broad bridge of skin attached in front to the chin and in the back to the skin over the ascending ramus. This bridge was moved upwards and sutured to the upper wound margin. Thus, a large defect was left under the floor of the mouth, which healed easily by granulation.

Dr. Charles H. Peck reported two instances which made him doubt, perhaps, the necessity of covering the inner surface with flaps of mucous membrane to prevent contraction.

A Cured Case of Cicatricial Stricture of the Esophagus.—Dr. Edward W. Peterson presented a male, about 22 years old, who had been employed as a "spieler" for a Coney Island show, and who drank some nitric acid by mistake. About eight days later he noticed that he could not swallow so-called hard food except with difficulty, and gradually he was able only to swallow soft foods. After a few weeks he had to live on fluids and at times even these would not pass down. Dr. Peterson said that several unsuccessful attempts were made to pass the stricture with various sized instruments. The stricture was located nine inches from the teeth. Finally, a small flexible bougie was introduced and, after a number of days of treatment, a No. 26 instrument could be passed. Following an attempt at divulsion with an esophageal divulsor,

the patient developed a cellulitis of the neck, which was followed by no ill results, but the lesson was taken to heart and the divulsion abandoned. The patient left the city, and when he returned he was greatly emaciated and unable to swallow water, except a spoonful at a time. All attempts to pass instruments failed. Finally, a thread was washed through the stricture into the stomach, a temporary gastrostomy was performed, the end of the thread fished out, and to it was attached a strong fish-line, which was drawn up through the esophagus out of the mouth. Several wire spindle bougies were then drawn up, and the stricture gradually dilated. Later, with a full-sized instrument in place, an internal esophagotomy was done, using the Abbe string method to chafe through the stricture. The patient was now free from any difficulty in swallowing, and now passed on himself once a week a full-sized esophageal bougie. The patient demonstrated the ease with which the bougie could be passed.

The Diagnosis of Imminent Perforation in Typhoid Fever.—Dr. Forbes Hawkes read this paper. Without going into the bibliography of the subject, the established facts warranted the following statement: The proportion of typhoid fever patients who had perforations varied in the different epidemics from 1 to 33 per cent., and probably from 6 to 10 per cent. was not far from the average. Osler had stated that one-third of the mortality in typhoid fever was due to perforation. Of this number about one-half might now be saved by operation if the most favorable conditions existed for early diagnosis and prompt surgical help. These favorable conditions were necessarily present to a greater degree in those hospitals in large cities that were provided with a corps of trained nurses in the wards, trained physicians on the house staff, and a sufficient number of attending surgeons for a prompt response to such emergencies. Operators agreed that every hour that elapsed between the perforation and the time of operation decreased by so much the patient's chances, and that other conditions being equal, good results should generally be obtained in operations done for ulcers that were either perforating at that moment or that had perforated just before. Any marked improvement, therefore, in the mortality records of these cases would have to come through a similar improvement in the diagnosis of the affection, or of the conditions which led up to the perforation. The so-called symptoms of perforation, "intense pain, marked tenderness, marked muscular rigidity or spasm, varying degrees of collapse, variations in the pulse rate and temperature, etc.," were in reality only the late symptoms of a previous peritonitis which had kept on developing many hours after the so-called perforation. It was his experience that the earliest symptoms of peritonitis in typhoid and in many other abdominal diseases were, as a rule, neither recorded nor noticed. Nurses should be carefully instructed to report to the house physician any pain in order that he might examine immediately for other signs of a beginning peritonitis. In a series of 500 cases observed in Osler's ward, McCrae stated that no pain existed in 208 cases (41 per cent.), and that pain existed during some time of the disease in 44 per cent. of the cases. If one considered abdominal pain alone it would help but little; other symptoms of a beginning peritonitis should be considered with it. He had seen a number of patients in whom other symptoms of peritonitis developed before that of pain; namely, muscular rigidity and tenderness, and in quite a number of cases the pain left before the muscular rigidity and tenderness, which persisted until the peritonitis had subsided. Even a very slight degree of muscular rigidity, when present *without pain*, should cause one to keep a watchful eye on the patient. If pain supervened, or if it existed at the time of the first examination, a surgeon should see the case at once, for two distinct danger signals were already set, and if they had localized abdominal pain and abdominal rigidity, they were almost certain to have one other symptom, tenderness. In many cases these were enough to warrant an exploratory operation if the patient was in good condition. The other diseases that were liable to occur in the abdominal region of a patient with typhoid fever that would give these three symptoms, without any peritonitis being present, were hysteria, lead colic, passage of a biliary or a renal calculus, and appendicitis without peritonitis (early). After ruling out these conditions one must look further for corroborating symptoms, as increased leucocytosis, slight shifting dullness in the flank, an increase in the blood pressure, etc. He said they were forced to conclude that a positive differential diagnosis of a perforative peritonitis or of an imminent perforation, was a very difficult matter, but a tentative one should be made much oftener than in the past at an early date, by examining the abdomen in the typhoid patients sufficiently often and with the utmost care. He believed the diagnosis of even mild peritonitis in a typhoid should mean operation and drainage if the patient was in a condition to stand it. After reporting two cases, Dr. Hawkes concluded that in many cases of typhoid fever a perforative stage of peritonitis was present which could be recognized as a beginning peritonitis if a sufficiently careful and a sufficiently frequent examination of the abdomen was made. They should divest themselves of the idea that the absence of pain in a given case ruled out any appreciable amount of peritonitis. Muscular rigidity and slight tenderness, usually localized, often preceded the symptom of pain by several hours. This prealgesic period would seem to be the very best period in which to institute peritoneal drainage of a loop of intestine with swollen ulcer patches, thus relieving the patient from the extra burden of the secondary infection and giving the ulcers a chance, if they were going to break down, to do so through a drainage tract. He stated that he had not intended taking up the symptoms of perforation in his paper, but of the preperforative period.

Dr. George E. Brewer believed that Dr. Hawkes had taken a great step in advance in the recognition of this preperforative stage in typhoid fever, and the report of his cases was interesting.

Dr. Joseph A. Blake said he had lately looked up the literature at Roosevelt Hospital, and found among 500 cases of typhoid fever the proportion of perforation was 48 to 100, a percentage which he considered quite high. He never felt sure of his diagnosis of the preperforative stage. When the three cardinal symptoms were present, *i.e.* pain, muscular rigidity, and tenderness, operation should be done. But it was often difficult to elicit these symptoms. If patients were apathetic, they would not complain of pain. Meteorism might be present, giving such a doughy resistance that muscular rigidity could not be determined. The diagnosis was exceedingly difficult. One should be satisfied to make a diagnosis of the perforation itself rather than to attempt the preperforative stage diagnosis.

Dr. Nydegger, U.S.M.H., called attention to the value of the leucocyte count in the diagnosis of perforation in typhoid fever. Often at the end of the third week the leucocytes number 7,000 or 8,000, some 3,000 below the normal. He saw a case of perforation two months ago at the Marine Hospital, where he was not sure of perforation, although he strongly suspected it. He made a number of counts, and found the polymorphonuclears had increased about 20 per cent. That count was made about three times, one hour between each count, and on the strength of this increase, operation was performed, the perforation was found, and closed.

Dr. Hawkes closed the discussion.

The Operative Treatment of Fractures at the Elbow (Lantern Slide Demonstration). Dr. Carleton P. Flint read this paper.

Dr. Joseph A. Blake said that in fractures around the elbow-joint a great many complications might occur, and no one should attempt treatment unless he was cognizant

of them. With regard to the time of operating upon these fractures, Dr. Flint took the ground that operation should be deferred from five to ten days to two weeks after the injury; Dr. Blake thought it was better to operate earlier. To be sure, there were certain objections, such as devitalized tissues, and one should be governed by the possibilities of infection in these cases. With regard to treatment, he used a drill which required very little force, and which did not interfere with the apposition of the fragments, an ordinary twisting drill. In fractures of the olecranon one was not so apt to have the interposition of soft parts as in fractures of the patella. The incision to be used must depend upon one's own experience in making these incisions.

Dr. George E. Brewer could recall no work on surgery which gave such rules or laid down such principles in the treatment of these cases, as did the paper of Dr. Flint. The paper covered the ground thoroughly, and would no doubt be a guide in the future in the treatment of elbow injuries. The lower end of the humerus furnished a great variety of injuries; they were very complicated and few could obtain increased functional activity of the joint, and any aid was to be desired. A good many of the cases Dr. Flint had operated upon had been under Dr. Brewer's observation, and, as a matter of fact, for the past six or eight months, at Dr. Flint's request, he had turned over to him the worst cases of vicious union and ankylosis that came in the hospital. It was from this very unfavorable class of cases that Dr. Flint had gotten his material. By intelligent operative treatment a great deal could be accomplished in fractures at the elbow.

Dr. Samuel Lloyd said he was much interested in this subject, and some time ago he had read a paper on it before this Section. He had had an experience with thirty or forty cases of fracture at the elbow, which had been followed by vicious results; in his experience he had never had a case of non-union in the young. He believed they should get away from the old-fashioned notion that the elbow should be fixed in cases of fractures; the position of the joint should be that which best held the fragments in apposition, no matter what that position might be. They then would have fewer cases with decreased range of motion, or fixation at the elbow.

Dr. John B. Walker said that oftentimes one would apparently not get good results in children, but at the end of three or four years better results followed.

Dr. Joseph Wiener called attention to a suture material, thin silver wire made into a cable, which made a pliable material, and was even stronger than a silver wire of the same caliber. In cases of fractures at the elbow he emphasized the fact that any one position could be maintained for any length of time.

Dr. Flint closed the discussion.

The Hand of Iron in the Glove of Rubber.—Dr. Robert T. Morris read this paper. (See page 304.)

Resected Gut; Silver Wire Filigree.—Dr. Joseph Wiener presented a specimen of resected gut showing the silver wire filigree, devised by Bartlet of St. Louis, in position. This filigree consisted merely of thin silver wire arranged in the form of a figure-of-eight with but one cross-piece.

SECTION ON DERMATOLOGY.

Stated Meeting, Held February 5, 1907.

Dr. A. R. Robinson in the Chair.

Acne Keratosa.—Dr. W. S. Gottheil presented this patient, a Russian girl 11 years old, five months in this country. She had suffered from the eruption since infancy; it had varied in severity at times, but had never entirely disappeared. Individual lesions lasted a long time (weeks or months), and then dried up, their hard tops falling off; and occasionally leaving a mark. Her general health was fair, her internal organs free. The history was defective, the child being an orphan. Scattered over the body were several hundred lesions, grouped in certain localities, and identical in appearance, though varying in size. The smallest were less than pinhead in size, the largest as big as a French pea. They were circular acuminate papules of a dull red color, on a normal skin base, and with a hard, yellowish-brown plug in their center. The largest papules tended to become irregularly circular or oval; and the central plug was large and hard. Even the smallest papules showed this central plug, removal of which left a cup-shaped glistening depression, and usually there was no pus. A characteristic feature was the formation of a lesion of precisely similar character, with reddened base and central hard plug, wherever there had been accidental lesions, such as scratches, these lesions assuming the elongated or irregular shape of the traumatism. The eruption was fairly well distributed over the body, but the papules were distinctly grouped in certain places. The largest collection of them was on the upper buttocks on both sides, where there were a hundred or two, mostly small in size. There were a fair number on the outer surface of the thighs, and some on the lower legs, especially about the ankles. The center of the back was free, but the shoulders and the skin over the shoulder blades showed large groups of lesions. There were a few on the upper anterior chest area, and more of them on the lower abdomen. The arms were markedly affected, especially the extensor surfaces; there were some on the flexor aspects, and many on both surfaces of the wrists. There were a large number of characteristic lesions on the backs of the hands. There were a few scattered over the face, as well as some scars that might have been the result of previous, possibly infected lesions. Palms, soles, and scalp were free. In 1904 Dr. Gottheil had described two cases of this affection, which is identical with the *acné cornée* of Hardy, Leloir, and Vidal, the *acné kératique* of Leredde and Tenneson, and possibly the keratosis follicularis contagiosa of Brooke. It differs from the ordinary lichen pilaris or spinulosus, in that the hyperkeratosis affects the sebaceous glands proper, rather than the hair follicles, and that the chronic inflammatory process is much more marked than in the pilous affection. In fact the microscopic examination in his earlier cases showed that the secretory ducts of the sebaceous glands were chiefly affected; the distended duct forming a sack that was pointed below, and broad and crateriform, and filled with masses of imperfectly cornified epithelial cells above. The sebaceous cells of the secreting portion of the gland below were compressed and atrophic. The chronic inflammatory process affecting the sebaceous glands seemed to be more nearly related to the acnes than to the pure keratoses; and it might be related also to the so-called cutaneous horns. In one of his earlier cases, the keratotic plugs at one or two places formed distinct, though minute, horny excrescences. Future study must decide whether it had any connection with acne necrotica or the tuberculides.

Keratosis of Palms and Soles from Arsenic.—Dr. Robinson presented a woman, aged twenty-seven years, who had had psoriasis of the whole cutaneous surface, except palms and soles, since she was six months old. The psoriasis was profuse over body. She had been under treatment ever since childhood. Sometimes the eruption was slight and again extensive, but had never occupied the palms or soles. Five years ago she took arsenic in increasing doses until she took eighteen drops of Fowler's Solution three times a day, and continued this amount for about two months, when an eruption appeared upon the palms and soles simultaneously, and remained to the present time, although the psoriasis nearly disappeared two years ago and again one year ago for a short period. According to the statement of the patient, an intelligent, educated woman, the eruption upon the palms and soles had not changed as regards the number of lesions since their

first appearance. They were confined to the palms and soles, were irregularly distributed, and varied in size from a pinhead to a small pea. Each lesion upon the palm was sharply limited, conical or flat in form, firm with a roughened or wart-like surface in central portion. There were no inflammatory symptoms present. The patient had been in the habit of cutting off the summit of the conical lesions when they caused annoyance. At the metacarpophalangeal junction ridges of calloused epidermis existed. Large areas of calloused skin were present on the soles in the usual places for normal thickenings from pressure. The long continuance of a single lesion in a definite shape without increasing in size, the warty character of the surface and the absence of inflammation, excluded psoriasis. Microscopical examinations of a small-pea-sized growth showed the corneous layer much thickened, with parakeratosis in parts; the stratum lucidum thickened, the granular layer well developed. Even over regions where the parakeratosis was present, the rete was increased greatly in thickness throughout the interpapillary rete prolongations extended deeply into the corium. The papillæ were not edematous, the papilla blood-vessels were dilated, but there was no marked infiltration, either of polynuclears or other bodies. The corium was normal, also the sweat glands in the corium. The warty character of the surface of the lesions depended upon the deep and broad furrows in the corneous layer from the dilated excretory sweat duct.

Dr. DILLINGHAM said that the case was very unusual and interesting, and that there was no question about the diagnosis being correct. He added that Dr. Robinson had not mentioned that the hollows of the feet were not involved, and that there was a marked callosity near the toes on the left foot about an inch long and one-eighth of an inch wide, formed by a number of lesions coalescing.

Morphœa.—Dr. WILLIAMS presented this patient, a woman twenty-eight years of age. She first noticed brown spots on her abdomen in the spring or summer of 1901, during her third pregnancy. They were about half an inch in diameter, smooth, not elevated, and showed no apparent thickening. They never disappeared, but were said to have become hard about six months ago: as there was a fresh outbreak of many sclerodermatous patches at that time, this statement may rest on faulty observation. Early in 1903 she noticed a hard, white swelling on the flexor surface of the left wrist, and others on the back of the right hand and the dorsum of the right foot. About two years later, hard spots developed between the shoulders and below each clavicle. These gradually became brown, and all softened while the woman was pregnant with her last child (born in November, 1905), leaving only a brown stain on the slightly dry but perfectly pliable skin. She felt very well during her last pregnancy and for some time after, but about six months ago the present eruption appeared. After this she worried about the condition of her skin, lost flesh and strength, and as she moved around more, she noticed a beginning prolapsus uteri. The first thing to call attention to a spot would be the itching, which sometimes was very severe. Scattered over the trunk were round, oval or oblong placques of thickened skin, brownish in color and slightly dry. The surface was even and firm, sometimes harsh. The border was fairly regular and faded rather quickly into the normal skin. Neither enlarged veins nor a violet border was observed. The spots on the left wrist and the right hand showed only a brown stain and slight atrophy. The pulse was eighty to the minute and regular. The thyroid was enlarged, but there was no exophthalmos. The urine was normal. The great improvement during the last pregnancy, and the evident enlargement of the thyroid were very suggestive of some relation between the secretions of these ductless glands and the disease, but the data available were too scanty to warrant any positive conclusion in this matter.

Keratosis Palmæ Hereditaria.—Dr. WILLIAMS presented a woman, her daughter, and her granddaughter, all showing this condition. The grandfather of the oldest patient was the first member of the family known to have had this disease. Three of his children, one male and two female, were affected, while two others, one male and one female, were free. Of his other children, no record could be obtained. The mother of the oldest of the patients presented, one of the affected females of the second generation, had nine children, of whom five, girls, were affected, while two boys and two girls were free. The second patient had two brothers, one affected and one free, and one daughter, the third of the patients shown. Of the fifty-nine descendants of whom a history was obtained, twenty were affected, and the others free. In no case, so far as could be ascertained, did the disease skip a generation: if any of the family escaped the disease, his or her children escaped also. The disease always appeared in infancy, the hands looking as if they had been soaked in water a long time, as the patient expressed it. The soles were generally free, but walking barefoot always excited the disease there also. Even with great care, sparing the hands as much as possible, the harshness and blackness persisted to a certain extent, but they were made much worse by rough work. The condition of the hands of the three patients presented was practically the same, differing only in degree. The backs of the hands were free, except over the joints, where the horny layer was slightly thickened and the natural lines of the skin exaggerated. On the oldest of the three the nails were rough and uneven, and there was a heaping up of horny matter beneath the free border. One of the little girl's nails was also rough, which was said to be the result of an old paronychia, and there was the same condition at the free border of the nails as in the grandmother. On the palmar surface the disease was most developed on the finger tips, and least on the hands. None of the patients showed the thick, horny plate which was so characteristic of the disease; instead, the skin was fairly pliable, the distinguishing features being a moderate thickening of the horny layer, with multiplication and exaggeration of the usual markings, so that the affected regions were divided by black lines into irregular polygonal areas.

Case for Diagnosis.—Dr. WILLIAMS presented this patient, an Italian, twenty-two years of age, three years in this country, a shoemaker by occupation. He denied ever having had a chancre, and gave no history of alopecia, sore throat, headaches, or eruption, until the present disease began. About ten years before, he first noticed a rounded elevation, about a quarter to a half inch in diameter, near the ulnar border of the dorsal surface of the right hand, at a point where the skin was irritated by the pressure of the thread he used in his work. In the next two months a similar lump appeared on the ulnar border of the right wrist, and a third about the middle of the dorsal surface of the right forearm, two inches above the wrist. This last lesion was cut out when it was about two weeks old, and has never recurred. Similar masses appeared on the back of the right hand, from time to time, up to two years ago. He said that none had developed since, but it was hard to communicate with him, and the details of the history were unreliable. The eruption was usually worse in summer, and it never disappeared entirely. For the past five years the patient had noticed a swelling over the back of the right wrist. From time to time during the past three years he had had an eruption on the neck, chest, and hands. Last year there was a patch about two inches in diameter on the back of the left hand, which healed without treatment. Four months before Dr. Williams showed him he had lost the sight of the left eye, complete blindness developing in a few minutes. Since that time he had been taking a medicine by drops, first ten drops three times a day, increasing to thirty drops, and under this treatment sight had improved. When presented there was complete loss of vision in the right half of the field of vision of the left eye, while the left half was

much restricted above. The eruption on the right hand had never been painful or tender, but the swelling and stiffness interfered considerably with the motion of the fingers. The eruption consisted of rounded dull red elevations, each surrounded with a red zone. All presented a crateriform opening at the top, from which serum oozed out. Two weeks ago they had discharged pus. Over the greater part of the area the inflammatory redness was continuous, and there was a moderate diffuse thickening. The border was irregular and ill-defined. The patient had taken mixed treatment for two weeks, and in that time the masses had shrunken greatly. Sections on microscopic examination showed an epithelioma, extending deeply into the subcutaneous tissue, and showing a very marked inflammatory infiltration in the corium and subcutaneous tissue. Cell-nests or pearls were very numerous. Smears from the largest round spot, and from the thin purulent fluid discharged from a smaller nodule were negative for tubercle bacilli, actinomyces, and *Spirochæta pallida*. Cultures gave a pure growth of streptococcus. Clinically, the lesions showed no resemblance whatever to epithelioma, and in spite of the pathological report, Dr. Williams believed that the diagnosis lay between tuberculosis and syphilis.

Dr. HUBBARD said that he thought this was a case of mixed infection of a chronic nature; and that the man's occupation, shoemaking, and his nationality, lower class Italian, afforded every opportunity for continued and repeated exposure to unhygienic conditions. He believed that treatment with a wet dressing of aluminium acetate would lead to speedy cure, and reported two cases of a similar condition, of eighteen months and two years standing, respectively, the second of which had been diagnosed as tuberculosis cutis, both of which healed in six weeks under that treatment.

Dr. DILLINGHAM said that the case bore no resemblance to epithelioma or to syphilis, and that he considered it tuberculosis verrucosa cutis.

THE PRACTITIONERS' SOCIETY OF NEW YORK.

207th Regular Meeting, February 1, 1907.

THE PRESIDENT, DR. ROBERT ABBE, IN THE CHAIR.

The Salt-Free Diet in Chronic Parenchymatous Nephritis.—By Dr. GEORGE L. PEABODY. (See page 381.)

Dr. BEVERLEY ROBINSON said he had read of a number of persons who had been on a salt-free diet, and they did not seem to like it on account of the lack of palatability of the food. He asked Dr. Peabody whether any of the cases he had reported had been followed up for any length of time, and if so, how long the relief from symptoms had lasted? The speaker said that in one case that had been communicated to him, there had been marked improvement under the salt-free diet, the patient's edema disappearing almost entirely, and the amount of albumin in the urine decreasing. This patient was an inmate of the Johns Hopkins University Hospital, and in order to test the value of the treatment one of the house staff gave him quite a quantity of salt in the course of twenty-four hours. This was followed by a rapid recurrence of the edema, and death. In this general connection, Dr. Robinson said, he wished to call attention to the important rôle that salt apparently played in the diet of certain animals, especially cattle.

Dr. LEWIS A. CONNER said that while he was thus far unable to speak regarding the permanency of the improvement that had followed the use of a salt-free diet in chronic parenchymatous nephritis, he was under the impression that it afforded more than simple transient relief from discomfort. He was inclined to regard it as a method of relieving the edema rather than the nephritis itself, but certainly the results of the treatment in these discouraging and almost hopeless cases had been very surprising. He recalled particularly two patients in his hospital ward. They occupied adjoining beds; both were suffering from general anasarca and severe dyspnea, requiring frequent tapping of the chests and abdomen, and for weeks every possible method had been tried to relieve their waterlogged condition. Then the salt free diet was instituted, and in both cases the anasarca rapidly disappeared; the patients were up and about in a few days, and finally left the hospital feeling well, although their urine still showed evidences of the nephritis. Dr. Conner said that in the cases he saw the patients were not at all disturbed by the lack of salt in their food. While they perhaps did not like it, they were perfectly willing to submit to the treatment. The speaker said that colonic irrigations of physiological salt solution, which had come to be regarded almost as a routine part of the treatment of nephritis, were, he thought, contraindicated in these cases of marked edema. Instead, a hypotonic salt solution should be used, or, better still, the sodium bicarbonate solution to which Dr. Peabody had referred.

Dr. PEABODY, in reply to a question as to whether the abstinence from salt in these cases implied a reduction in the quantity of fluid taken, said that it usually coincided with a restriction as to fluids. These patients, as a rule, bore the restriction of fluids very well. In all of the cases where the treatment had been tried, the albumin in the urine decreased in quantity, although it did not always completely disappear. No claim was made that the treatment had any curative effect on the kidneys; it had merely a transient effect upon a serous and distressing symptom.

Dr. ANDREW H. SMITH said we should have to accept the conclusion that anasarca was due to some condition of the tissues themselves, and not to the blood pressure or any condition of the blood or blood-vessels. There was no reason for believing that under certain conditions the fluid of the blood transuded more readily into the tissues, but rather that there was something in the tissues themselves that led to the accumulation of the fluid, and perhaps the observations made by Dr. Peabody and others supplied the necessary explanation for such phenomena. If there was a quantity of salt distributed all through the tissues, making them greedy for water, we had reason enough for anasarca. The beneficial effects of the salt-free diet also offered a very reasonable explanation of the good results of a milk diet in the treatment of certain nephritic manifestations. In confining a patient to milk, he was practically given a salt-free diet.

Dr. FRANCIS P. KINNICUTT said the results of the salt-free diet treatment reported by Dr. Peabody were very much in accord with those of Drs. Miller and Kelly, and while they might not be permanent, they were at least very desirable, as they relieved these patients of their most distressing symptoms. Laboratory tests had shown that in healthy individuals the sodium chloride balance was easily maintained, even with very rapid and decided variations in the sodium chloride intake, and it had also been shown that this balance was not maintained in the presence of certain renal disturbances. Under the latter conditions the salt accumulated in the tissues and edema appeared. Dr. Kinnicutt said that if the salt-free treatment afforded even temporary relief to this class of patients it would be a great advance in our therapeutics.

Dr. H. NEWTON HEINEMAN of Naul[illegible], Germany, said the effect of salt upon healthy cattle, to which Dr. Robinson had referred, would have no bearing upon its use in pathological conditions, such as those that formed the basis of Dr. Peabody's paper. The beneficial effects of the salt-free diet in the treatment of certain kidney lesions would probably find their explanation along the lines indicated by Dr. Andrew H. Smith, and outside of the blood-vessels themselves. The weight factor and one that was frequently lost sight of in connection with the facts of this paper was the lymphatic pressure. While the con-

dition of the capillary blood-vessels and circulation was, of course, exceedingly important, and doubtless explained many pathological conditions, we should not lose sight of the fact that variations in the lymphatic pressure were probably a most important factor in the immediate cause of the exosmotic changes that the reader of the paper had discussed. The speaker said he thought it not at all unlikely that a good deal of our advance in medical knowledge during the next decade would be made in connection with changes in the lymphatic circulation, with which the tissues dealt more immediately than they did with the capillary circulation. The osmologists, of which Zirkel was a brilliant exponent, were doing the work. Studies by others, such as continued by him for three years and not yet concluded on urinary cryoscopy, with investigations of the urine freezing point, would certainly advance renal pathological knowledge. Dr. Heineman said that in the treatment of heart cases he was no longer content with producing heart compensation, but tried to bring about body compensation, which meant a proper relation between the ebb and tide flow of the entire circulating medium, of which the heart was an important part, but still only a part. The results obtained by Dr. Peabody by his salt-free method of treatment were certainly excellent. In discussing the ultimate effect of the treatment, the speaker said there was no question but that even the temporary relief from pressure of a kidney that was diseased would give that organ a chance to recover itself. He had frequently seen examples of this at Nauheim, where the albumin, with hyaline and even slightly granular casts, would disappear from the urine after proper regulation of the patient's diet and habits; this would ofttimes effect a proper regulation of the circulation, without the necessity of resorting to treatment directed toward the kidneys themselves, and he could recall cases where it had prolonged life in the face of a very bad prognosis.

Dr. Peabody, in closing, said there was no reason to believe that salt-free diet in cases of chronic parenchymatous nephritis had any permanent curative effect. On the contrary, there was every reason to believe that if these patients resumed their usual occupations and habits of diet, the anasarca would return. The most rational outlook of the treatment was to ascertain in each individual case how much salt that particular patient could take without producing edema, and limit the intake to that quantity. The probabilities were, however, that such a fixed amount would not be permanent, because, as time passed on, the kidneys would probably degenerate more and more. Dr. Peabody said he had never seen a case of chronic parenchymatous nephritis at any period of life that fully recovered, and the most that could be hoped from this method of treatment was to relieve the distressing symptoms of these patients, and perhaps render them fairly comfortable and even give them a chance to resume their occupations. There was no reason why this treatment should not be maintained more or less permanently, as the natural food contained a reasonable amount of salt. Dr. Peabody said that in one of the cases reported in his paper the patient was a boy whose anasarca was very marked indeed. The edema involved the genitals, and the face was swollen to such an extent that the eyes were nearly closed. The anasarca disappeared entirely in about two weeks under a salt-free diet. The boy was then ordered 1 gram of salt daily, and there was no recurrence of the edema. He was then given two grams daily, and there was no recurrence. The dose was then increased to three grams daily, and this was followed by a gradual recurrence of the edema. This experiment seemed to indicate that this child could safely take two grams of sodium chlorid daily, but that he could not tolerate beyond that limit, taking no account of the salt which was present in his meat, milk, and other articles of food.

Modern Hospital Construction—with Lantern Illustrations.—Dr. W. Gilman Thompson read a paper on this subject, which he illustrated with numerous lantern slide illustrations of hospital construction in this country and abroad. He called attention to certain advantages of the pavilion type of hospital, of which the Policlinico at Rome and the new Virchow Hospital at Berlin were good illustrations. They each were constructed of more than fifty buildings, one or two stories high, and while this type of institution increased the original cost for land, it promised a better classification and grouping of cases. Many of the modern hospitals that he had visited in Europe were remarkable in their completeness, and included every possible facility for the most advanced methods of investigation and treatment. Dr. Thompson said the most encouraging advance in modern hospital construction was that the interests of the individual patient were considered paramount. It implied an intelligent consideration of the needs of different groups of patients, and an appreciation of the fact that fresh air and environment had to go hand in hand with medication in order to obtain the best results. The entire subject could be epitomized in the motto that appeared over the entrance of one of the great German hospitals, namely, "In the treatment of the disease, do not omit to treat the man."

College of Physicians of Philadelphia.

At a stated meeting, held February 6, Dr. John H. Musser read a paper entitled "Infections Within the Thorax—Empyema." He dwelt on the relation of this disorder to antecedent pneumonia and pleurisy, as well as to typhoid fever, scarlet fever, measles, and other infectious diseases. Its presence was to be suspected when the signs of a collection of fluid of greater or lesser extent persisted after the subsidence of the primary affection, especially if there was a continuance, and particularly an exacerbation of the leucocytosis that previously existed, or if such a leucocytosis developed when previously there had been none. The x-ray might prove of service here by showing a shadow that was to be referred to the purulent accumulation. Often the physical signs were related to the fissures between the lobes, where collections of pus were prone to form. In addition, there were likely to be chills, fever, and sweating, with cough and pain, and emaciation. Exploratory puncture might fail to disclose the presence of the pus, and often it was necessary to resect a rib, after which the introduction of forceps or the finger would succeed in evacuating an abscess, while the establishment of satisfactory drainage would lead to eventual recovery. Dr. Theodor Schott of Bad Nauheim read by invitation a paper entitled "The Treatment of Chronic Diseases of the Heart." He pointed out that adequate results were often not obtained from the treatment of chronic diseases of the heart by mere rest in the recumbent posture and proper restriction of the diet, while the drugs commonly employed, namely digitalis, strophanthus, strychnine, and the like, while useful, were not curative. As a result, resort must often be had to physical methods of treatment, such as exercises of one sort or another, and bathing. Great care must be taken in the employment of these measures, and the needs of the individual case should be always fully considered. Dr. Schott described the various forms of thermal and carbonated and saline baths available at Nauheim, and also the form of gentle resistance exercises applied in suitable cases. By means of charts he illustrated the reduction in the size of dilated hearts observed in actual cases as a result of both the baths and the exercises. In his opinion, the favorable results of the treatment were to be attributed especially to the tonic effects produced upon the muscular system including the myocardium. While it was to be preferred that the treatment should be carried out under the most favorable conditions such as were to be found at Bad Nauheim, it could also be carried

out satisfactorily at the patient's home if applied with intelligence and gentleness. An approximate artificial reproduction of the baths could be made by means of the saline constituents prepared in such a form as to secure the generation of carbon dioxide, and by adjustment of the temperature and the proper proportions of the several saline constituents of the natural waters.

New Instruments.

A SUCTION AND INSTILLATION SOUND, FOR USE IN THE TREATMENT OF CHRONIC POSTERIOR URETHRITIS WITH INVOLVEMENT OF THE PROSTATIC FOLLICLES.*

By W. D. TRENWITH, M.D.,

NEW YORK.

GENITOURINARY SURGEON TO OUT-PATIENT DEPARTMENT, NEW YORK HOSPITAL.

Cases of urethritis in which the prostatic urethra has been involved, especially those where many of the follicles have been infected and which have become chronic, will offer in many instances a condition exceedingly difficult to overcome, necessitating a long course of treatment, with the outcome problematical, and discouraging alike to patient and physician.

Such a case will present but few subjective symptoms; there is but little if any complaint of pain or discomfort; the urine is mostly clear, but floating about in it are numerous "tack-like" bodies, floating with head down, the contents of certain of the prostatic follicles, which have been extracted or expressed during micturition. If they are examined under the microscope they may show the presence of gonococci and pus cells, or only pus cells, but if pus cells alone are present it is probable that, though gonococci cannot be demonstrated, they are nevertheless lurking in the depths of the follicles. There may also be present shreds and threads, due to erosions, hyperplasias, or catarrhal conditions of the posterior urethra, or to a similar state of affairs in the anterior portion of the canal.

The prostate is either normal in size, or somewhat enlarged, or boggy, indicating recent or comparatively recent inflammation.

The previous history of the case is that of anterior urethritis, with extension to the posterior urethra, and with or without inflammation of the prostate.

As to the treatment of these cases, the balsams do no particular good; hand injections are not serviceable, except perhaps to help to eradicate a subacute or chronic anterior urethritis, which may exist at the same time, because the injected fluid does not reach the diseased area in the posterior urethra. Benefit is derived from retrojections or irrigations of silver nitrate and permanganate of potassium, or instillations of solutions of picric acid, silver nitrate, or sulphate of copper in varying strengths; massage of the prostate; the passage of either warm or cold sounds; suppositories of ichthyol or ice; rectal irrigation with hot or cold water; general tonics.

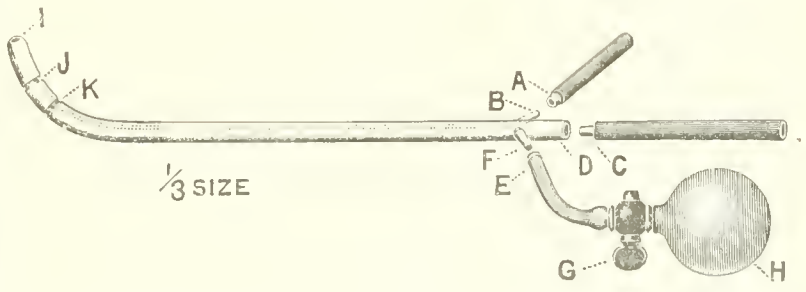
*Presented before the Riverside Practitioners' Society, November 13, and the West End Medical Society, November 24, 1906.

In spite of our efforts, however, progress is usually at best but very slow, and the reason for this is, in my opinion, that our methods are faulty in this respect, that in most of the treatments suggested above not all of the infected follicles and diseased areas are brought within the sphere of action of the medicinal or mechanical measure used at each treatment.

In massage, the follicles on the posterior wall of the prostatic urethra only are acted upon, while those on the anterior wall are in no way affected; when an instillation is used, because of the apposition and folding together of the mucous membrane of the urethra, a good many infected follicles and diseased areas must of necessity escape the medication at a given treatment; moreover, the medication will with difficulty penetrate to the depths of the diseased follicles, and then probably only those from which the contents have been expressed or extracted during micturition; suppositories, rectal irrigations, and tonics are measures which aid in a general but not in a local way.

Of the methods suggested above the most good follows the use of the sound, or retrojections and irrigations, and the reason is plain, for in both methods the mucous membrane is acted upon throughout its whole extent, and consequently a greater number of diseased follicles, erosions, and hyperplasias are brought under treatment.

Because of these facts and as an aid in the treatment of these cases, I have devised the instrument,



of which a cut is here presented, and which was made for me by the Kny-Scheerer Co.

The instrument consists of an outer shell (No. 25 of the French scale, in this particular one, but it can be made in any size from 20 to 30) and two inner tubes, D-I and B-J. Between the outer shell, which has the shape of a sound, and the inner tube D-I is a space, the only openings to which are the fine holes indicated in the narrow but deep groove at K, and through the nipple at F. The tube B-J passing through the nipple at B, and the space between the outer shell and the tube D-I, ends by a single small opening in the very narrow and deep groove at J; it is made of silver and is quite small. The grooves at J and K are made very narrow and deep, so that when the instrument is in place it will be impossible for the mucous membrane to lie in contact with the surface of the groove, but will rather be stretched across it, leaving a small cavity between the membrane and the bottom of the groove.

When the instrument is in place in the urethra the air is exhausted from the rubber bulb H, and E is firmly attached to the nipple at F, the bulb is then allowed to expand. A tendency to form a vacuum is at once produced, a suction is exerted on the mucous membrane covering the groove K, and the contents of the follicles are drawn out or at least loosened. The instrument is then slowly

withdrawn, at the same time, A being firmly joined to the nipple B, any desired strength of silver, copper, or picric acid solution is instilled through the tube B-J, by means of an instillation syringe attached to the distal end of the rubber tube A.

The fluid instilled will medicate the mucous membrane covering the groove at J throughout its whole extent; moreover, the membrane being still on the stretch, after the suction exerted upon it at K, and the follicles being emptied, or, if not emptied, their contents at least loosened, the mouths of the follicles will still be open and the fluid instilled will penetrate to a greater degree into them, and so attack the gonococci which lie at the bottom of the follicle, or act upon the loosened contents so that when next the patient voids the contents of his bladder they will be more readily washed out. Likewise any ulcerated or denuded areas in the urethra are stretched and the medication is applied to all portions of the area.

If it is so desired, any solution thought to be necessary can be introduced into the bladder through the tube D-I, after the instrument is in place, and before commencing to withdraw it; the solution can be prevented from escaping by joining C and D and closing the distal end of C with either a pinch or stop-cock.

An occasional patient with a small meatus will complain of pain when the instrument is introduced, as the grooves pass the meatus, otherwise patients tell me in answer to my inquiries that they experience no more inconvenience or pain than is felt in the passage of an ordinary sound of the same diameter.

It is not claimed for this instrument that it is a cure-all, or that it is suitable in every case, but only that it is suitable in selected cases of the type which has been described above, and that it is of considerable aid and value when so used.

The points of value which this instrument possesses are in my opinion as follows:

1—The ability to inject into the bladder any desired solution before beginning further treatment.

2—The beneficial effect produced by extracting or loosening the contents of all of the diseased follicles on both the anterior and the posterior wall of the prostatic urethra.

3—The medication of the mucous membrane while it is on the stretch and the penetration of the medicinal fluid into the follicles.

4—The benefit to be derived from the passage of a sound.

5—The ability to use any one or all of the procedures outlined above in but one manipulation of the urethra.

Cysticercus Cellulosæ in the Tongue of a Child.—L. De Gaetano describes a rare case of cysticercus cellulosæ in the tongue of a child of ten years. The child had associated with dogs and other animals, but there had been no symptoms of tenia in the child or any other members of the family. For two years there had been noticed a nodule on the left side of the tongue, which latterly had grown rapidly until it was the size of a large nut. It was covered by normal mucous membrane, hard, and embedded in the muscle of the organ. When enucleated it was found to constitute a cystic tumor with a firm capsule, from which on cutting there flowed a limpid liquid, and the internal surface was covered by a yellowish-white membrane, at one portion of which was located a small white mass, the egg of the tape-worm. The larva must have reached the stomach or duodenum, when it was liberated by the digestive juices and the animal must have migrated to its permanent location by way of several other organs.—*Rivista di Clinica Pediatrica*

THE OCULAR LESIONS OF GENERAL ARTERIOSCLEROSIS.*

BY WILBUR B. MARPLE, M.D.,

NEW YORK.

OPHTHALMIC SURGEON NEW YORK EYE AND EAR INFIRMARY; CONSULTING OPHTHALMIC SURGEON BABIES' HOSPITAL.

THE retinal changes in arteriosclerosis were referred to first by Hirschberg[1] twenty-five years ago (his case showed white lines along the arteries, with fine glistening points). But even before that Loring, in 1873, Nettleship, in 1879, and others had pointed out that in the development of circulatory disturbances in the retina local changes in the vessel walls played an important rôle. The investigation of Thoma[15] have shown that changes in the veins invariably accompany the changes in the arteries; in other words, that we have a phlebosclerosis as well as an arteriosclerosis. Strictly speaking, therefore, the term angiosclerosis would be the proper term to use. Inasmuch, however, as in general the arterial changes in the retina have the greater significance in the diagnosis of general vascular changes, I shall use the term "arteriosclerosis." These changes are more apt to affect isolated retinal vessels, or a short length of one of these while all the other vessels may be normal. As Mr. George Coats says, "nothing emerges more clearly from pathological research than the fact that angiosclerotic processes are almost always exceedingly irregular in their distribution."

Let us now consider in detail the various ophthalmoscopic signs of arteriosclerosis. There may be:

(1) A general change in the size of the arteries and veins of the eye-ground. The narrowing of the arteries may be slight in the early stages, or in marked cases it may be extreme, so much so as to almost suggest atrophy of the optic nerve, especially if there should be any pallor of the disc,

FIG. 1.—*a*, Silver wire arteries; *b*, white lines along the vessel; *c*, tortuosity of the vascular twigs; *d*, dilatations of vessels; *e*, constrictions of vessels; *f*, beading of artery; *g*, compression of a vein by the overlying artery; *h*, *h*, hemorrages. All of the lesions shown in this illustration were found in the hemiplegia cases referred to below; some of them in many of the cases. Several were sketched from these patients.

*Read by invitation before the Medical Association of the Greater City of New York, in a Symposium on "General Arteriosclerosis," January 21, 1907.

The apparent diminution in size of the arteries is associated with changes in the coats which have narrowed the blood stream. As the disease affects some parts of the artery more than others, irregularity in caliber takes place, and this has been found to characterize arteriosclerosis in other parts of the body.

In contrast to the narrowing of the arteries, the veins often appear relatively dilated, and often are actually so, this dilatation of the veins occurring in about 50 per cent. of all cases. In sclerosis of the aged, the veins are apt to be larger on the average in the periphery than in the vicinity of the papilla, and on the latter. Normally the arteries are about two-thirds to three-fourths the size of the veins, whereas in advanced cases of arteriosclerosis (for example, in contracted kidney), they may be only one-half to one-third the size of the veins. In addition to this narrowing of the arteries, there may be a tortuosity of certain small arterial branches, especially in the vicinity of the macula. Often the larger vessels from which these very tortuous branches arise are themselves normal. These corkscrew arterial twigs are apt to appear in the early stages of the condition, for in the very advanced cases, with pronounced ridigity of the vessels elsewhere, there is apt to be no tortuosity.

(2) There may be changes in the color of the arteries. That is, the central light streak of the arteries is broader and of increased distinctness, and the whole surface of the vessel is of a somewhat lighter color than normal, as if there was an unusually bright reflection from its coats. It is usually the secondary and tertiary branches of the central artery that are mainly affected. These are the so-called "silver wire" arteries; and the appearance is due to the higher reflecting power from the arterial wall after it has undergone a hyaline or fibroid change. (Fig. 1*a*, and all arteries in upper half of figure; contrast with those of lower half.)

(3) There may be changes in the caliber of the vessels at different points, and this is the most characteristic phenomenon. The most common point at which such change is noted is where a vein is crossed by an artery (Fig. 1*g*). In the early stages of arteriosclerosis, the first abnormality noted is a loss of the light streak of the vein on either side of the artery, with possibly a trifling diminution of the venous caliber under the artery. (Fig. 2*b*.) Often, also, a thickening and opacity of the arterial walls is evident, inasmuch as the vein is obscured where it passes under the artery, whereas under normal conditions the underlying vein can be detected through the translucent artery. An artery under a vein becomes visible on account of the brighter reflex from its walls. In more advanced cases the vein is very much constricted (Fig. 2*a*), winds around the artery, and often the marked twist is very conspicuous, as oftentimes the rest of the vein is not at all tortuous. As Rachlmann[2] points out, the venous narrowing is the result of a phlebosclerosis, limited to this point, which may be caused by the mechanical interference with the blood current at the point of crossing of an artery, perhaps by the walls of the latter. It is also probable that the abnormally high tension of the arteries, which in arteriosclerosis comes with the pulse wave, assists in the compression of the vein under it. That the vein is here compressed and the current hindered is evident from the venous dilatation back of the narrow part (see Figs. 1 and 2), as well as by the frequent hemorrhages often seen exclusively in the area of an obstructed vein. Sometimes when a vein passes over a rigid artery, the former flattens out somewhat like a strap. (Fig. 2*c*.)

As is well understood, the retinal vessels are suspended in a completely transparent tissue, as is the case nowhere else in the body, and this makes their examination especially valuable to the clinician. Under normal conditions the vessel wall is quite invisible. Only the blood column is visible, and the wall is recognized merely in the appearance of the light reflex which is influenced by the form or curve of the wall. The changes in the vascular walls in ocular arteriosclerosis may be of two kinds, visible and invisible. In the latter the vessel walls are still transparent, but we detect the changes by the alteration in the size and shape of the blood column. Among the *visible* changes are white lines along parts of some vessels (it may be for a considerable distance), arteries or veins or both (Fig. 1*b*). Sometimes almost the whole diameter of a vessel is changed into a white cord, and often glistening points are seen along it. When this change is limited to the branch of a vessel the diameter here is greater than that of the normal part of the vessel. This opacity of the vessel walls can be more readily made out with a plane mirror and a weak illumination.

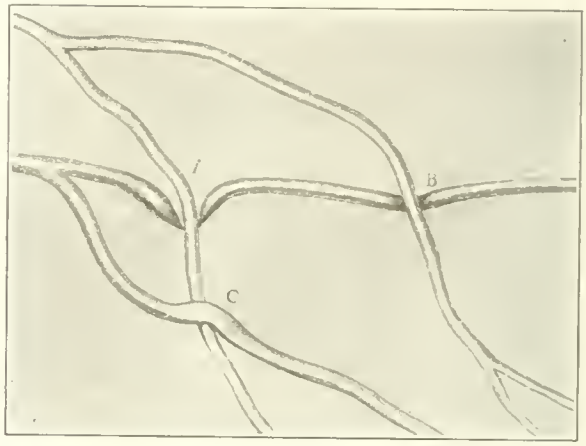

FIG. 2.—*a*, Marked pressure in late stages (this is from a patient seen during the last week), *b*, slight pressure of the vein by the artery; *c*, like appearance of the vein passing over the artery.

Besides these visible opaque changes in the vessel walls, we meet with localized and marked narrowing of the retinal arteries and veins, limited to a short section of the vessel (called by Raehlmann, "arteriosclerosis nodosa"), seldom equal in length to the diameter of the optic nerve, more frequently one-half or one-quarter this length (Fig. 1*e*). Nothing is seen of the markedly thickened vessel wall, but the abnormally narrowed blood column points to the thickening of the walls. There is, then, a broad and a narrow part of the vessel, the latter looking as though it were constricted by a band; sometimes two broad parts are united by an extremely thin part, and in advanced cases the blood column seems to be completely broken at certain points. We may have circumscribed constrictions of the blood column where the blood column is of a very minute caliber or apparently disappears (Fig. 1*e*). As Raehlmann says, where such changes limited to small portions of a vessel are seen ophthalmoscopically, the diagnosis of a local vascular narrowing by endarteritis can be positively made.

Sometimes the vessel presents knob-like irregularities in caliber, like a string of beads (Fig. 1*f*).

As Mr. George Coats[3] has recently pointed out in a very suggestive paper on "Intraocular Vascular

Disease," the pathology of these two changes in the vascular walls is different. In the cases of white lines along the vessels ("periarteritis"; "perivasculitis"), we have a "fibrosis" in which the connective tissue wall becomes greatly thickened, and encroaches more or less *concentrically* on the lumen of the vessels. The narrowing of the lumen, on the other hand, which is indicated only by a narrowing of the blood column, and not by any visible change in the walls, is due to proliferation of the endothelium, and this is almost always eccentric, the lumen being occluded on one side. In one of Hertel's[1] cases, fully half of the lumen of the central artery on the disc, was occupied by such a proliferation of endothelium springing from one side, as shown in a section. As Coats points out, the two conditions are probably due to different causes. Disease (with proliferation) of the intima is most probably a response to a circulating toxin, which would naturally affect the internal coat; thickening of the connective tissue wall is probably a strengthening of the wall to compensate for raised blood pressure. As these changes tend to strengthen the wall, he asks why does hemorrhage result? It would seem probable that it does not occur at the actual seat of disease, but the changes cause obstruction to the circulation, damming back of the blood and rupture at some spot where the wall is unthickened, or in the capillaries where the wall is incapable of much thickening. The result is a retinal hemorrhage.

While the "localized narrowing of the arteries" is only indicated in many cases, by a "localized narrowing of the blood column," there is little doubt but that we have to do with an endothelial proliferation and thickening of the walls. Quite a number of such cases have now been examined anatomically, where ophthalmoscopically the artery was very much narrowed, and microscopically the vessel showed proliferation of the endothelium. But, as Mr. Coats says, our knowledge stands in need of extension by more cases of the same kind worked out vessel by vessel, with careful reference to the clinical appearance.

Finally, we have aneurysmal dilatations or varicose ectasiæ of vessels which may be oblong, or sac-shaped, and two to four times the normal caliber (Fig. 1*d*). These are occasionally seen in the arteries, more frequently in the vein. When seen in the arteries, these dilatations are often seen on the central side of a constriction, and have been caused by the increase in blood pressure, due to the proliferation ahead. In the veins they would be on the peripheral side of a constriction for a similar reason.

In addition to these vascular changes we have the progressive venous pulse, described by Raehlmann among the first. This is visible, not only in the central venous branches, but also in the periphery of the fundus, and on all the larger branches of the veins. Immediately after the radial pulse the diameter of the vessel becomes dilated quickly, to collapse slowly, the collapse occupying most of the interval between two pulsations. In marked cases the vein when dilated is more than twice as thick as when collapsed, and the fluctuation in caliber can be followed in equal rhythm along the whole course of the vessel. When this progressive venous pulse is conspicuously present, the physiological venous pulse on the disc is absent. This symptom is the expression of the pulse-wave transmitted abnormally far into the rigid vessels of the sclerosed arteries which act through the distended capillaries upon the veins.

As the result of these various changes in the vessels themselves, we may have hemorrhages (Fig. 1*h*) and opacity or infiltration of the retina, especially in the vicinity of the macula. This superficial whitish or greenish discoloration of the retina at the posterior pole appears frequently where the small vessels running from the papilla to the macula are diseased. There is often just enough of this to prevent a good fundus reflex, so that often we have to use a mydriatic to make a satisfactory examination. It is something like, though much less marked than, the edema in embolism of the central artery of the retina. Mr. Marcus Gunn[9] suggests as an explanation of this infiltration or retinal edema, that the increased difficulty in arterial circulation will diminish the rapidity of the blood stream in the capillaries and veins, resulting in a tendency to the escape of liquor sanguinis into the surrounding tissues. The walls of the capillaries become more permeable, and diapedesis of blood cells takes place, and we get hemorrhages.

As Mr. George Coats says, it would seem probable that hemorrhages do not occur at the actual seat of disease, but the changes cause obstruction to the circulation, damming back of the blood, and rupture at some spot where the wall is unthickened, or in the capillaries where the wall is incapable of much thickening.

Liebrecht, Otto, and others have suggested that not a few cases of atrophy, also, according to Bull,[10] many of the cases of so-called chronic simple glaucoma are due to retrobulbar arteriosclerosis of the internal carotid, ophthalmic, or anterior cerebral arteries, which by pressure on the optic nerve posterior to the foramen has caused the descending atrophy.

Considering these various ocular evidences[5] of angiosclerosis, de Schweinitz[14] in a recent valuable paper makes a useful division of the lesions into those which are *suggestive* and those which are *pathognomonic*. In the former he includes uneven caliber and undue tortuosity of the retinal arteries, increased distinctness of the central light streak, an unusually light color of the breadth of the artery. The pathognomonic signs include changes in the size and breadth of the retinal arteries of such character that a beaded appearance is produced, distinct loss of translucency, decided lesions in the arterial walls, consisting of white stripes in the form of perivasculitis; alternate contractions and dilatations of the veins, and, most important of all, the indentation of the veins by the stiffened arteries. This latter symptom is recognized by all observers as the one ocular symptom most nearly pathognomonic of angiosclerosis. As Mr. Marcus Gunn says, however, it is only when several of these signs which have been described are present together that we can assert positively that the arterial change is very important.

Age.—Angiosclerosis is not confined exclusively to elderly people, for healthy-looking retinal vessels are frequently seen in persons seventy or eighty years of age. While the majority of cases are met with in old subjects, occasionally it is seen in persons under forty, or even thirty years of age, and it has been seen in a patient under twenty. In the presence of nephritis or syphilis, it can occur even earlier. As Mr. Coats says, it is in part a senile change, which we would expect to find in the vessels of any old person, in part a definite response to a pathological stimulus, and these two components are not always clearly separable. Given the stimulus, however, it may appear far in advance of the

usual age as, for example, in juvenile nephritis. In other words, the mechanical conditions of the blood current only lead to the changes described when a predisposition exists and the vessel wall is pathologically ready for the changes.

Vision.—The vascular changes may be very pronounced in both arteries and veins without any evidence of functional disturbances or defect in the visual field. In one of Hertel's cases, examined microscopically, the proliferation on the inner wall of the central artery was so considerable as to occlude fully one-half of the lumen of the vessel. Yet the vision was 20/20. If considerable visual impairment occurs, this is apt to come on suddenly; it may be from a hemorrhage at the posterior pole or it may be from venous thrombosis. These cases of venous thrombosis are especially prone to glaucoma subsequently. Of sixteen cases of venous thrombosis examined microscopically by Mr. Coats, glaucoma occurred in all sixteen. Sudden loss of vision may come on also as the result of obstruction of the central artery of the retina by endarteritis. These cases were formerly thought to be due to embolism. But we now know that many, perhaps most of them, are the result of *endarteritis obliterans* accompanying arteriosclerosis. (While this is undoubtedly true, I am in thorough accord with Mr. Coats and other English observers, who hold that our German confrères go much too far when they affirm that embolism of the central artery has never occurred. Several cases which have been reported are undoubtedly of this nature.) Many of these cases have had prodromal obscurations of vision, possibly for many years, before the final loss of sight. These obscurations often come from cardiac weakness, and in many cases are reparable, temporarily at least, by cardiac stimulants. Wagenmann[16] reported an interesting case of arteriosclerosis (with large veins, white lines along the arteries, and hard radials), who had suffered from prodromal obscurations for a long time. Wagenmann saw the patient during a sudden attack of complete blindness lasting a half hour or more. The arteries were invisible except near the disc (that is empty), and the veins reduced to fine lines, and there was opacity of the retina, with a red spot at the macula, as in embolism. Gradually the circulation returned, with restoration of vision.

These cases of ischemia and temporary blindness, due to vascular spasm in association with arteriosclerosis, have been occasionally reported by others, and have been benefited by nitrite of amyl.

Location of the Lesions.—The central vessels, those nearer the optic nerve, are the most apt to be affected, possibly, as Raehlmann suggests, because it is easier to discover the changes in vessels of a larger diameter. But Hertel's anatomical investigations have demonstrated a more marked involvement of the vesesls in the central portions. While the proliferation of the intima may occur where there is no nearby bifurcation, yet it is in the vicinity of such bifurcations, especially where they branch almost at right angles to one another, that they are most frequently met with.

Frequency with which Ocular Lesions are Found in General Arteriosclerosis.—Raehlmann examined 210 cases of arteriosclerosis, and found aneurysmal dilatations in only two cases. In almost 50 per cent. of the cases he observed either whitish borders to some of the vessels (20 per cent.) or aneurysmal dilatations, or local narrowing of the caliber (21 per cent.). Hirschberg[1] examined fifty persons, between the ages of sixty and eighty years, and found that 46 per cent. of the persons examined showed changes in the retinal arteries (44 per cent. showed changes in the caliber of the arteries at some points of their course); 2 per cent. showed white lines along the vessels. Friedenwald[5] examined twenty-three patients for Preston, and he reached conclusions practically the same. And yet, in our textbooks on diseases of the eye it is very unusual to find any reference to this important subject.

The writer has been much interested in the result of an examination which he recently made of forty-six patients, most of them suffering from hemiplegia, a few from paraplegia. In such a class of cases it would be fair to suppose that the condition had been attended with arteriosclerosis of the cerebral vessels. Of the forty-six patients, six had such considerable lens changes as to make a satisfactory examination of the fundus impossible. Of the remaining forty (of whom the oldest was seventy-four and the youngest forty-one), sixteen, or 40 per cent. showed pressure of the veins by the arteries, often to a very marked degree. Twelve, or 30 per cent., showed this same symptom associated with local constrictions or varicosities of the vessels. Perivasculitis was seen twice (5 per cent.) and beading of the vessels twice (5 per cent.), so that out of forty such cases, pathognomonic ocular symptoms of arteriosclerosis were discovered in thirty-three cases, or 83 per cent. In seven cases (or 17 per cent.) the *suggestive* symptoms alone were found, viz., dilated veins and small, brilliant arteries. But in all of these the symptoms were most suggestive; that is, the veins were very much dilated and the reflex from the arteries was most brilliant. In a number of cases the lesions were almost as numerous in one and the same individual as is represented in Fig. 1, and the opthalmoscopic pictures were often exquisite. Yet not many of them could have been recognized in the indirect method. In not one case (though I looked very carefully for it) could I discover Raehlmann's symptom of progressive venous pulse, and I am not positive that I have ever seen it in any case, and yet Raehlmann states that it occurs in 50 per cent. of the cases of arteriosclerosis.

Sex.—As is true elsewhere in the body, these retinal changes of angiosclerosis occur more frequently in males than in females.

Limitations.—In the first place, the mistake must not be made of attributing all vascular changes found in the retina to angiosclerosis, for frequently such are of a local character. On the other hand, it would be equally a mistake to consider the absence of ophthalmoscopic evidence of retinal changes as positive proof that arteriosclerosis was not present in the eye or elsewhere in the body. For we know how irregular in its distribution arteriosclerosis is, and, furthermore, Hertel examined a large number of old people in whom no abnormality was visible, with the ophthalmoscope; and nevertheless the changes of arteriosclerosis could be demonstrated microscopically in a considerable number of these.

Significance of these Changes.—So far as the eye is concerned, we find that glaucoma occurs very frequently in this condition of arteriosclerosis. It must be remembered that if acute glaucoma occurs in an eye in which the retinal changes of arteriosclerosis are present, a very guarded prognosis must be given in case of iridectomy is done. For often the condition of the vessels is such that intraocular hemorrhage follows operation, resulting in the loss of the eye. But these retinal changes become very

much more significant from the assistance they render us in diagnosing a serious *general* condition, it may be before it has been suspected by the general physician. It is very well understood to-day that the diagnosis of many cases of nephritis is first made by the oculist, often at a time when the patient may not have shown any other evidence of the disease. Here the renal condition is an angiosclerosis, and, as Michel first demonstrated, the retinal changes are also due to vascular degeneration. But it is not alone in renal disease, but also in general arteriosclerosis that the ophthalmoscope gives us valuable information, for here alone are the minute capillaries of the body visible. (The largest retinal vessel has a diameter of not more than 1-100 of an inch.) General arteriosclerosis affects the internal carotid very frequently, and is very apt to involve its principal branches, and among these the ophthalmic and cerebral arteries. If these degenerative processes can be demonstrated in the retina, it is very probable that the same disease is present in the cerebral vessels. Of forty-four cases of Raehlmann, there was subsequent cerebral hemorrhage in ten, or 21 per cent. Mr. Marcus Gunn, in a valuable paper, reported fourteen cases of intraocular vascular disease, in which cerebral hemorrhage subsequently occurred, and we have all of us met with many similar cases. It is with these patients that the responsibility of the oculist becomes very great, for it is manifest, as de Schweinitz points out, that he has an important duty to perform in connection with them. For if evidence of beginning arterial degeneration is discovered ophthalmoscopically (very often such discovery is made accidentally, it may be, in examining a patient for glasses), the matter should be brought to the attention of the patient's medical adviser, so that a careful investigation of the arterial tension and of the renal condition may be made. Thus, oftentimes proper treatment can be applied with the greatest benefit, and possibly an impending catastrophe be averted or postponed. It cannot be too strongly emphasized that examination of our middle-aged patients for glasses should not be done in a perfunctory manner. We should investigate not only the optical needs of all such patients, but of equal, if not greater importance, is it that we investigate most carefully the condition of the retinal vessels, and ascertain whether or not there are present any ocular evidences of arteriosclerosis.

The narrowing of vessels over a short course, possibly limited to a part of the optic nerve, is not easily discovered, and can readily escape our notice unless looked for very carefully. The indirect image cannot be used, and even with the upright image it often requires an expert observer to recognize the differences in caliber, which are not infrequently the only evidence of the changes, and not seldom must a mydriatic be used. As Raehlmann says, "when sclerosis of the retinal vessels is suspected, it is necessary, in order not to overlook the changes, to carefully examine each separate vessel, especially in its central course." If every oculist searches for these changes in all his patients he will find some of these in an increasing percentage of his cases.

In conclusion, we may say, with Mr. Gunn, that "ophthalmoscopic examination is one of the most ready means for the early detection of important arterial changes." The method of examination is infinitely more delicate than palpation of the radial or temporal arteries through the skin. We are thus able to diagnose with great probability by the ophthalmoscope a vascular disease which is at the bottom of many cerebral disease processes, often threatening the patient's life. Inasmuch as the vascular change very frequently is limited to the internal carotid and its branches, we are therefore sometimes able to diagnose the dangerous affection of the cerebral vessels with the ophthalmoscope when the rest of the vascular system does not show the disease.

SOME REMARKS ON THE RADICAL MASTOID OPERATION FOR THE CURE OF CHRONIC SUPPURATION OF THE MIDDLE EAR.*

By SEYMOUR OPPENHEIMER, M.D.,

NEW YORK.

OTOLOGIST TO GOUVERNEUR HOSPITAL, LARYNGOLOGIST AND OTOLOGIST TO THE SYDENHAM HOSPITAL AND TO MT. SINAI HOSPITAL DISPENSARY; FELLOW OF THE AMERICAN LARYNGOLOGICAL, RHINOLOGICAL, AND OTOLOGICAL SOCIETY, FELLOW OF THE NEW YORK ACADEMY OF MEDICINE.

To determine when a radical operation should be performed for the cure of a suppurating middle ear which has continued for a longer or shorter period, is undoubtedly one of the most serious problems with which the otologist is confronted, for not only is the question complicated in many ways, but the difficulty of convincing the patient that such an operation is essential, when he is conscious of possibly only a slight aural discharge, not infrequently results in failure and serious if not fatal complications may ensue.

In the selection of cases for the radical operation, it has well been said that a large experience, rather than any rigid rules, is the best safeguard against the risk of delay, or of performing an unnecessary operation. That this statement is essentially true may be admitted, for while general indications may be formulated, yet each case must be judged upon its individual merits and the particular treatment in that case carried out accordingly. The radical operation, therefore, must be accepted or rejected upon the merits of the individual case, based necessarily upon broad general rules that bear a more or less close application to every case of chronic suppurative otitis, but it may be safely said that it should be resorted to in almost all cases which cannot be cured by measures less radical in nature.

While formerly intratympanic operations of various sorts were much in vogue for the treatment

*Read at a meeting of the Harlem Medical Association, January 2, 1907.

of this condition and yet have a definite field of applicability, it is undoubtedly more and more being recognized that in many cases such measures must fail on account of the inability to remove in this way all the morbid tissue and the remaining nidus of disease is a further focus of infection keeping up the suppuration. While in this condition, therefore, the various intratympanic procedures formerly vaunted have steadily lost ground as curative measures, yet in probably the majority of cases of chronic tympanic suppuration they are undoubtedly indicated and even to the most ardent advocate of the radical operation it must not be lost sight of that not infrequently in suitable cases local antiseptic and surgical treatment, such as the removal of granulation tissue, polypi, circumscribed areas or carious or necrotic bone and the extraction of the carious malleus and incus, produce a cessation of the suppuration.

Many instances of this aural affection are encountered in which, except for an irregular amount of purulent discharge from the ear, pursue a practically symptomless course for many years, and yet when such cases have been operated on for various reasons, after the course of years, it has been found almost without exception that the tympanic cavity is not alone affected, but that even more serious morbid changes have taken place in the antrum and mastoid cells, and that these changes, including destruction of large bony areas, have been progressing without the patient or even the physician having the least knowledge that such was the case. In other instances the discharge disappears after a longer or shorter period of treatment through the auditory canal and may remain absent for a very long time, to again return following infection through the Eustachian tube from a coryza, or often the recurrence cannot be traced at the time to any direct source. It is in these recurrent cases, with temporary cessation of purulent discharge, that one is most apt to be deceived as to the measures to be adopted, and also as to the pathological changes that are taking place, for in many instances of this type the patient believes that his disease is cured when the discharge disappears, while as an actual fact the condition is only temporarily in abeyance and active morbid changes are apt to become prominent at any moment.

The question as to the necessity of performing a radical operation for the cure of aural suppuration in the absence of active complicating symptoms is more and more becoming answered in the affirmative, as this operation is undoubtedly the safest and most efficient method of eradicating such a condition and with proper aseptic precautions and technique it is not dangerous to life, and in the majority of cases operated upon the results are entirely satisfactory. The more the pathology of aural suppuration is appreciated the more will active, radical measures be instituted early and necessarily the less will cases of so-called incurable chronic tympanic suppuration be encountered. And for the same reasons experience has shown that with a greater number of cases operated upon the more clearly differentiated becomes the indications and the more clearly is shown its practical value.

In order to obtain the desired result from this operation certain objects must be attained, the most important being that all diseased tissue of whatever nature, whether osseous or otherwise, be thoroughly removed, for unless this is done a recurrence may be always expected. A most important object, and one which intratympanic operative procedures do not as a rule accomplish, is the securing of free and permanent drainage. Of less importance, but still of sufficient gravity to the patient, is the retention of such hearing as may remain, and while this is but a subsidiary object, yet in most instances the radical operation conserves or even improves the auditory perception. In addition one should always bear in mind the great indications for the radical operation is the relief of a serious menace, not only to the health of the individual but also to his life. To obtain successful results, therefore, with certain and rapid healing, it is essential that the diseased areas be eliminated and that the tympanum, antrum, and mastoid cells be converted into a single cavity, with smooth walls, in which there are no recesses, so that every part is readily accessible from the enlarged auditory canal.

The advantages of this operation over other procedures in chronic tympanic suppuration cannot be overestimated, as in the larger proportion of cases it admits of the complete and permanent cure of the aural disease, while in such cases where for various reasons success has not been complete at least all the parts are exposed to view and full opportunity offered to locate and later eradicate any diseased areas which might have escaped observation at the time of the primary operation, or which have developed subsequently. The conditions are made such that asepsis can also be maintained to a much greater degree than would be possible in any other manner, and as the result of the removal of pyogenic tissues from the vicinity of dangerous points the healthy osseous tissue remaining forms an efficient barrier against any danger of an extension of the infection to the intracranial structures.

While in general the indications for the radical operation are sufficiently clear, it is impossible to lay down guiding rules for all cases; yet by careful differentiation the advisability of operation can usually be determined, and it is desired here to indicate as far as possible such rules as may be of value for this purpose. Undoubtedly the indications as enunciated by Politzer form the basis of this subject at the present time, and these may be divided into two main groups, the objective and the subjective. Of the former which indicate operative procedures in order to cure the suppurative process present, marked caries of the tympanic walls, the recurrence of granulation tissue and polypi after its removal in the vicinity of the aditus, the presence of fistula in the mastoid cortex and marked cholesteatomata are to be cited, while hyperostosis of the external auditory canal, facial paralysis or paresis, and well marked symptoms of acute mastoiditis, are also not compatible with local treatment through the canal. In addition, also indicating operation, are those cases with prolonged fetid suppuration resisting less radical measures, and especially is this called for if there is a perforation in the superior segment of the membrana tympani, or if the remnants of the membrana are adherent to the inner tympanic wall, and still more is operation indicated if pus or epithelial masses can be drawn from the region of the aditus. Symptoms of intracranial complications are, of course, of sufficient warrant for radical operative procedures, irrespective of other signs.

Of the subjective symptoms indicating operation associated with more or less of the former manifestations the following may be considered in this connection: Persistent pain in the ear or in the mastoid region, especially if increased by percussion and if involving the occipital or parietal regions;

permanent or intermittent vertigo and cerebral symptoms such as headache, torpor, etc.

In many patients with chronic otorrhea the question of immediate operation, or the advisability of delay for a shorter or longer time, will often prove most puzzling, but in those cases where there is a reinfection, or the chronic suppuration undergoes a period of activity with more or less rapid extension of the pathological process, then it is necessary that the radical operation be promptly performed. In the presence of any of the usual grave complications, one should never delay removing the focus of the disease and at the same time the measures adopted should be of sufficient extent as to remove the possibility of further suppuration. Debatable and open to question as regards the performance of an immediate operation are those cases where the patient suffers little or no pain and when no symptoms of mastoid changes are apparent, but even in such individuals it must be recognized that serious changes may be in progress and yet not be apparent, so that if the osseus lesion is at all extensive it is always proper to err on the side of safety and remove all the diseased tissue by a radical operation, rather than adopt tentative and so-called conservative measures which in no wise will eradicate the disease. In this connection it must always be remembered that the attic, aditus, and antrum, which in many instances bear the brunt of the purulent inflammation, are an essential portion of the tympanic cavity and as a result of their anatomic relationship bear a large share in all the infectious changes that take place in the latter.

Stetter believes that the radical operation is indicated when there is marked dizziness, with disturbance of gait, and when there is nausea and vomiting, while as far as local symptoms are indicative of such a procedure the duration of the disease should be seriously considered, as should also the condition of the posterior aural region, the frequency of attacks of pain, the presence or absence of facial paralysis, and the nature and quantity of the purulent discharge. Jackson advocates this procedure in the absence of mastoid symptoms, when the suppuration has failed to yield in three months after ossiculectomy, followed by the so-called wick treatment, Milligan believing that operation should be performed when the suppuration has persisted for one year, and when for at least three months careful and rational local treatment has been employed without influencing the course of the suppuration. This difficult problem is elucidated by Macewen in a satisfactory manner, when he states that when a pyogenic lesion exists in the middle ear or in adnexa, which is either not accessible, or cannot be effectually eradicated through the external auditory canal, the mastoid cells and antrum ought to be opened.

While operation is undoubtedly necessary when symptoms of septicemia have commenced, or where there is dead or carious bone in the tympanic cavity in whatever location that may be and accompanied by repeated attacks of serious symptoms, or when there is evidence of involvement of the mastoid structure either of long or short duration, yet there is a large class of cases of aural suppuration in which these symptoms are absent, but in which I believe this operation is also indicated in order to obtain a complete cessation of the purulent discharge. In this group belong those cases in which one obtains certain evidence of the presence of dead or seriously diseased bone in the attic or other portions of the middle ear, but is unable to obtain a clear history of symptoms that would indicate serious outbreaks in the past. While in the other class, which comprises those with persistent otorrhea, but in whom manipulation through the canal does not furnish satisfactory evidence of osseous lesions and one obtains a fairly clear history of the absence of any intercurrent exacerbations, it may be difficult to always decide that the indications warrant radical operation, but as a rule in selected cases of this class a permanent cessation of the discharge cannot be obtained in any other manner.

When the symptoms are but slight, whether objective, or subjective, or combined, one must not only be guided in solving this question by the aural symptoms alone, but it is always the wisest plan to carefully study and weigh the general condition of the individual and also his social relations. In individuals in whom the aural suppuration gives evidences of a tuberculous basis, or in those in whom the otorrhea pursues an asthenic course almost from its inception, prolonged local treatment through the canal, or delay in waiting for active symptoms to arise so that clear indications for operation may be obtained, is always advisable; these cases are especially liable to have extensive osseous lesions, and it is always the best policy to operate early, not only to cure the suppuration, but also to avoid the development of serious complications.

When the secretion from the middle ear contains cholesteatomatous masses and from time to time these block the perforation in the membrana tympani, or produce symptoms of pus retention higher up in the aditus or antrum, it is clearly established that little success can be obtained by measures, operative or otherwise, carried out through the external canal, as the morbid changes are either too extensive or the pathogenic areas are inaccessible portions. It has been repeatedly shown that the proliferating epithelial masses are not only derived from the covering of the osseous surfaces, but that they proliferate and penetrate for some distance into the structure of the bone and can only be completely eradicated by removing this upper layer of osseous tissue, so that the radical operation alone can be relied upon to give complete access to all diseased parts.

In the absence of symptoms other than that of a persistent otorrhea associated with more or less foul odor, one must be guided in deciding upon operation by the fact that continuous treatment has not diminished or abolished the discharge, and not by the nature of the discharge, its quality, or quantity, or by the odor, it being a well-known fact that the virulency of an otorrhea cannot always be judged by the amount of the discharge or its odor, although in the presence of a profuse, continuous discharge one is warranted in opening the mastoid. In those cases where the odor is persistent and not at all, or but little, altered by treatment through the canal, radical operation is undoubtedly warranted, as the continuous presence of such an odor implies that there is decomposing pus being retained in inaccessible parts, or that carious bone is present.

There are certain exceptions to the performance of the radical operation when otherwise indicated for the cure of a suppurating otitis in the absence of marked symptoms which should always be heeded and the treatment of the diseased ear conducted accordingly. It is absolutely contraindicated in advanced cases of pulmonary tuberculosis, or when other serious organic diseases are present, while in the very aged individual, where the discharge has lasted for a long time without apparent

inconvenience, it is perfectly reasonable that such surgical intervention should not be considered.

That the operation is not without danger, even in the otherwise healthy individual, cannot be gainsaid in all instances, as it is a trying surgical procedure. It incapacitates the individual often for long periods of time; there can be no surety that the hearing will improve following it, and even with the operation apparently carefully performed the purulent discharge may still continue owing to a progressive osteomyelitic process taking place. A negative danger may be mentioned and that of not having all the diseased tissue thoroughly removed, or the operation being incompletely performed. Paralysis may follow injury to the facial nerve, or the semicircular canal may be injured, with its train of serious consequences. One should guard against unavoidably opening the lateral sinus, or exposing the middle cerebral fossa, and particularly against injury or removal of the stapes and thus exposing the internal ear to the dangers of serious infection. With all this, however, the danger is not as great to the patient as the presence of a continual focus of suppuration in the temporal bone, and one is perfectly justified in saying that the "danger lies not in the operation, but rather in its neglect."

That failure is unavoidable in some cases must be granted from the nature of the pathological changes present, but even if a small proportion are not completely relieved of the discharge, and the operation fails to produce a permanently dry and epidermized cavity, the patient undoubtedly is in a much safer position than before, as all foci and recesses where purulent material may develop have been eradicated. The concealed parts, which before operation were not accessible, or were in part difficult of access, have been fully exposed and are rendered capable of being accurately treated under the sight of the otologist.

In the absence of acute symptoms or complications where the radical operation is advised for the cure of the persistent suppuration, the question of the effect upon the hearing will strongly influence the action of the patient. Where tests show that the hearing is already seriously impaired and the labyrinth is involved, nothing will be gained as far as the hearing is concerned by this operation, but where the inner ear is normal and the patient can hear ordinary conversation fairly well, the majority of cases operated upon show no further impairment of auditory acuity, but rather an improvement. A small number of individuals will, however, suffer from still greater impairment following the operation, but practically this should receive little consideration, as the elimination of the suppuration and of the dangers to health and life which exist even in the uncomplicated case far outweigh the further impairment of what is in the majority of such cases an already impaired hearing.

While it is not desired here to discuss the operative procedure itself in any way, yet certain technical difficulties present themselves that must be overcome before successful results can be obtained, and it will be well to briefly mention these. The most important of these is the difficulty of cleansing the newly formed cavity of all diseased tissue, for unless this is done thoroughly the future outcome is seriously jeopardized, so that in performing this operation one should be especially careful to eliminate all suspected areas of caries or necrosis, rather than to take the chance of a recurrence by allowing a suspicious area to remain. Of these particular areas where carious tissue is apt to be overlooked, it is important to see that the outer wall of the attic is thoroughly removed, as at this point a carious process of the osseous tissue is very frequently found. Not only must the tympanic cavity, aditus, antrum, and mastoid cells be converted into one chamber, but the posterior and superior walls of the external auditory canal must be removed to accomplish this thoroughly, and in addition the remnants of the tympanic membrane, with the malleus and incus if still present, must be entirely taken away. In some cases it is especially important to open up and remove groups of pneumatic cells situated in various locations not usually considered to be involved, and of these the posterior group of mastoid cells should be especially explored. It is also highly important that the cell, or group of cells, at the tip of the mastoid process be eliminated, as in many cases of chronic suppurative otitis without mastoid symptoms at any time it will be found on operation that a focus of diseased tissue, or confined pus, exists at this location.

Thus will the operative field depend entirely upon the condition of the mastoid tissues, as in practically every case of long standing otorrhea the mastoid will be found involved to a greater or lesser degree, and to this point, therefore, should the operation be primarily directed. As a result of constantly carrying out an extremely radical principle in operating it has been found time and again, in the absence of serious local symptoms, and often when the patient is apparently in perfect health, that grave and extensive destruction has been going on in the osseous interior, even to the extent of exposing the intracranial structures, so that the operation has clearly shown that one does not always appreciate the danger in which these patients stand until the parts are exposed to view.

45 East Sixtieth Street.

THE ABORTIVE TREATMENT OF PNEUMONIA.

By G. LENOX CURTIS, M.D.,

NEW YORK.

MEMBER OF THE AMERICAN MEDICAL ASSOCIATION; AMERICAN ELECTROTHERAPEUTIC ASSOCIATION; AMERICAN ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE; NEW YORK STATE MEDICAL ASSOCIATION; MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK; HARLEM MEDICAL ASSOCIATION, THE SOCIETY OF SOCIAL AND MORAL PROPHYLAXIS.

For the reason that, in the language of another, "the divisions of the various diseases of the lungs have not been finally settled," and because, for the sake of diagnostic accuracy, many different forms of pneumonia are recognized and described, I wish it to be understood that the statements contained in this paper refer to and include any pneumonic disease, either acute or chronic, which is characterized by exudation into the alveoli and bronchioles, and which results in consolidation and uselessness of the affected area.

Like every other disease, pneumonia is the result of two kinds of causes: the exciting or accidental, as exposure to changes of temperature or to atmospheric conditions; and the predisposing, essential, or specific which consists of vitiated secretions, with their accompanying germs and defective elimination. Von Jürgensen, in speaking of croupous pneumonia, says, "It is a general and not a local disease, the inflammation of the lungs being the principal symptom."

Another authority, who evidently believes the specific cause to be a germ or its secretions, says: "If it were possible to prevent the entrance of the pneumococci into the alveoli of the lungs, pneumonia

would be impossible," and regretfully states that any method of preventing such an occurrence is unknown.

To combat and remove this latter class of causes is the chief therapeutic problem, and the success which attends this effort is the measure of the physician's skill and usefulness. That, taking the profession as a whole, our failures equal if they do not exceed our successes, is a sad commentary upon prevailing methods of treatment. The mortality of pneumonia under any mode of treatment which, to-day, is upheld by the sanction of authority, is appalling; but, to me, no more so than the satisfied indifference with which the majority of the profession pursue, year after year, lines of treatment which statistics prove to be, at best, but little better than pure expectancy.

Why are these unworthy and unreliable methods complacently persisted in when it is so painfully evident that they are wrong, and that greater success is impossible unless means of a radically different character are employed? In no other line of endeavor, professional or otherwise, is such indifference to success exhibited or tolerated. What lawyer, teacher, minister, or dentist is there who would not consider himself disqualified for his position if over 50 per cent. of his undertakings continually proved to be flat failures?

The ordinary physician, however, is not disconcerted by so small a matter. Like the brook he goes on forever, continually treating pneumonia in the same old way, in spite of his confessed inability to do no more in the way of assisting nature to overcome this scourge of civilized humanity.

Although they do not excuse it, there are two reasons for this professional apathy. One is that, in the therapeutic department of medicine, the physician has always been taught to accept as proper whatever form of treatment tradition and authority have decided to be best, and that any deviation from methods thus prescribed constitutes a species of heresy, the punishment of which is professional ostracism. Because of this fact, original thinking and individual investigation are hindered and the professional conscience blunted. The other is that the acknowledged leaders of medical thought and practice are so intensely jealous of their ideas and reputation that, with very few exceptions, they cannot be induced either to accept any modification of the methods they advocated or to investigate without prejudice the merits of any system of practice which radically differs from their own.

The following personal experience—one of many—serves both to illustrate and corroborate the statement just made. In talking with a well-known physician of this city—one who is both an author of distinction and a professor in one of our medical colleges—about the possibility of reestablishing activity in a consolidated lung in tuberculous cases, he not only spurned the idea that such a thing could be done, but when I offered to demonstrate the fact to his entire satisfaction, coolly and unblushingly said: "Rather than acknowledge that what I have taught and written is wrong, I would retire from the practice of medicine." When such narrowness and bigotry exist in the minds of medical teachers, is it any wonder that so many physicians, young in practice, meet with so little success in their efforts to cure the sick?

With regard to pneumonia, I have been waiting for years for some eminent general practitioner and teacher to come boldly forward with some definite and scientific plan of treatment by which the number of cures will, at least, equal the number of failures, but, so far, I have waited in vain.

In presenting my own methods of treatment, I do not wish to censure too severely the older members of the profession for what seems to me to be, upon their part, a lack of careful study of the nature and cause of this serious malady, or to reprove them for adhering to lines of treatment which result in such a high death rate. I do desire, however, to urge the younger members of the profession either to adopt the therapeutic methods I have found so successful, or, by research and experiment, to discover and formulate a better one.

There are two circumstances which account, in a great measure, for the high percentage of mortality which attends the treatment of pneumonia by prevailing methods. The first is the frequent failure to recognize the fact that, in the form in which it usually presents itself, pneumonia is, as Von Jürgensen has stated, a general as well as a local disease, and therefore remedies addressed to the lungs alone, no matter how appropriate and reliable they may be, must often fail to effect a cure. The second is the lack, which has heretofore existed, of a safe and reliable remedy for the removal of congestion. Congestion implies not only stagnation, but chemical deterioration of all of the fluids in the affected area, of the interstitial fluids as well as of those within the capillary vessels. The successful remedy, therefore, must be one which is able, speedily, to remove both of these morbid conditions.

Until recently drugs have been almost the only means available for this purpose, but now more efficient measures are at command. The chief of these, according to my experience, is the ozone-producing, electric current. This remedy, with its method of application, was fully described in a paper entitled, "The Influence of Electroözonation upon Disease," which I read before the New York Academy of Medicine, and which appeared in the *New York Medical Journal* in the issues of January 25 and February 1, 1902.

For the benefit of those who have not seen this article, the following brief outline description of the apparatus by which ozone is generated must suffice:

The machine consists, practically, of an ozone generator fed by a high-tension coil which multiplies the voltage of the commercial current a million or more times and practically eliminates all amperage. To the generator are attached brushes or corrugated wires from which ozone is given off in large quantities, and also connected with it, by means of a wire cord, is a Geisler vacuum tube through which ozone is forced into and through the body, thereby oxidizing all pathogenic products and reestablishing nutrition and vitality. Connected with this apparatus is an electric cabinet which generates light and heat coupled with ozone. Thus, the most important elements which enter into the problem of life are supplied in a form to be utilized.

I find ozonation to be an ideal remedy for all stages and degrees of congestion. Being the result of very rapid vibration, it possesses both physical and chemical qualities in the highest degree of efficiency. By virtue of its vibratory quality it penetrates to, and mechanically acts upon, every cell of the affected region. By urging forward the sluggish contents of the capillaries it equalizes and restores the capillary circulation; by stimulating osmosis, it compels excessive accumulations, of whatever nature, to reenter the circulatory vessels and once more become a part of the active, systemic circulation, and, by contracting and strengthening the muscular walls of the relaxed and distended

capillaries, it enables them to maintain their circulatory function in a more perfect manner.

At the same time these mechanical effects are taking place, others of a chemical nature, resulting from ozonation—the most active and most effective form of oxidation—are occurring. Not only are the abnormal accumulations which have been deposited at the seat of congestion oxidized and destroyed, but the morbific elements in the blood *which constitute the specific cause* are similarly dealt with.

Ever since I fully appreciated the remedial value of this form of ozone, it has been my chief reliance in the treatment of pneumonia. My experience with it comprises over sixty cases, taken as they came, at any stage of the disease, and covering all degrees of severity, with complete recovery in every instance. Several of the cases were in well developed tuberculous patients; some had organic disease of the heart, and one, a case of septic pneumonia, occurred in a patient ill with puerperal fever complicated with a pelvic abscess. One patient, considered hopeless when I was called, was taking a combination of thirteen different drugs and only a teaspoonful of whiskey every two or three hours. In spite of this there was complete recovery. Resolution was established in twenty-four hours; the lungs were free and the heart action normal. The patient was up and out in two weeks.

In another case of double pneumonia, complicated with tuberculosis in the primary stage, the patient recovered and went back to business in two weeks. In regard to age, several of my patients were over seventy-five and one was ninety.

As further evidence of the efficacy of ozonation in this disease, I will cite, in detail, its results in a very severe typical case to which I was called when the patient, who was eighty-nine years old, was supposed to be dying. She had been under treatment for six weeks, confined all of the time to her bed. She was thoroughly exhausted, and, when first seen, was unconscious. The lungs were fairly clear, respiration 32, pulse weak, fluttering, and intermitting every second beat. There was great restlessness with muttering delirium and involuntary discharges from both the bowels and bladder.

Within half an hour from the beginnig of treatment by ozonation, the pulse intermitted only every seventh beat. Within an hour, the involuntary action of the bowels and bladder ceased. Half an hour later, the pulse beat at 90, with no intermission, and the patient fell into a quiet, restful sleep, for an hour and a half, from which she awoke conscious and asking for nourishment.

She received but two treatments daily, but made a complete and uninterrupted recovery. So rapidly did her strength and vitality return that, at the expiration of a month, she was able to take a long journey by rail without the slightest unfavorable result. Her health, since recovery, has been better than for years before the illness occurred. She is now in her ninety-second year, hale and hearty. Her physician remarked that the treatment she received at that time "seemed immediately to bring into activity all conditions favorable to the reproduction of life and vitality."

In acute cases, recovery is more rapid; complete restoration being effected generally within five or six days. Even in those frequently occurring, serious cases of tardy and incomplete resolution, in which, on account of the low vitality, the solidification that has occurred fails to be absorbed and remains a constant menace to the life of the patient, ozonation will establish resolution in a few days, the entire area affected becoming free and clear.

The case of Dr. Robertson, the principal features of which are mentioned in my paper upon "The Influence of Electroözonation Upon Disease" above referred to, illustrates its action in this class of cases. On account of his low vitality, the doctor's recovery from a severe attack of pneumonia was incomplete, the middle lobe of the right lung remaining consolidated. Several weeks after he was able to leave his bed, his pulse was 100, temperature 99.1°, respiration 24. There was an irritable cough with scanty expectoration laden with pus. His physicians believed he was going into a decline, and advised him to give up practice and spend the remainder of his life in the South—a step which he had made preparations to take.

At this juncture, he was brought to me for treatment by his physician who, however, doubted that ozonation could be of any benefit to him. On April 19, 1901, within twenty-four hours after the first treatment, the temperature rose to 105°, accompanied with all of the pneumonic symptoms attending such a high degree of fever. This was followed by abundant expectoration to such an extent that, within the next twenty-four hours, he had thrown off over a quart of offensive, "prune-juice" mucus, and all consolidation had disappeared. Within five days from the first treatment, all râles had disappeared, and not even the slightest roughness could be heard. Strange as it may seem, on April 23, only four days after the first treatment, the doctor replaced his sign in the window, unpacked his furniture, and resumed practice. His health was completely restored by fifteen treatments.

The high temperature which appeared in this case so soon after the first treatment, always occurs in a greater or less degree in cases of this class. It is not caused by an aggravation or encroachment of the disease, as might be supposed. It is, rather, an indication of the increased vitality which ozonation has conferred upon the system, and is due to the successful effort made to establish resolution and to get rid of the consolidation; the intensity of the effort being determined by the degree of vitality which has been acquired and the character and amount of the consolidation to be removed.

This clinical record, comprising over sixty-nine cases of pneumonia treated, with 100 per cent. of recoveries, would seem to be sufficient to establish the fact that there is a rational and successful method of treating this heretofore unconquered disease; so that, now, instead of dreading it, as was formerly the case, on account of its rapid development and frequently fatal termination, I consider it one of the easiest diseases to cure.

It is frequently stated that pneumonia cannot be aborted; that it must always "run its course." While this is probably the case, without exception, in the practice of those who make this statement, I can assure you that such an opinion is erroneous. I have repeatedly demonstrated that, by the proper application of ozonation, pneumonia can be aborted at any stage, resolution becoming established within forty-eight hours from the beginning of treatment. I desire to add, parenthetically, that in my opinion there is no reason, but incompetent treatment, for allowing any acute disease to get well by limitation. Any form of treatment which cannot largely discount nature's unaided efforts, is neither rational nor scientific; it is decidedly worse than no treatment at all.

Ozonation should be applied from half an hour to two hours at a time, and repeated several times daily, according to the severity of the case, but never so frequently as to interfere with a proper

amount of sleep. It should be applied over the head, spine, and abdomen, as well as over the congested area; over the cerebrum and medulla, because it clears the mental faculties and stimulates the nerve centers which control both respiration and motion; over the abdomen, because it augments the activity of the eliminative organs; and over the congested lung area which can be accurately outlined by the painful sensation caused by passing the electrode over it, because it oxidizes and removes the inflammatory deposits.

In treating pneumonia, I do not rely entirely upon any single remedy, however efficient. I give my patients the benefit of anything which I have found can be safely depended upon to remove congestion, reestablish normal circulation in the affected organs, and eliminate effete matter from every part of the system.

As pneumonia is usually precipitated by a chill to the surface of the body, causing congestion of internal parts, artificial heat is an auxiliary remedy of too much importance to be neglected. A profuse and prolonged sweat, at the appearance of the first symptoms, often proves sufficient to bring the disease process to a sudden and favorable termination. Maintain the heat by any practical means; keep the patient's room, which should always be well ventilated and ozonized, at a *tropical temperature* (100° or more of Fahrenheit). The patient should be kept constantly in a mild state of perspiration until resolution is fully established.

There are many ways of doing this. If the patient is able to sit up, a vapor bath may be given. When unable to assume an upright position, the same results may be obtained by burning a few ounces of alcohol under the bed clothing in a shallow cup or saucer which is allowed to float in a deep, narrow vessel partly filled with water to prevent the vessel from breaking. Care must be taken that the bedclothes are raised and supported a foot or more over the patient and so arranged that only the head is exposed and the heated air surrounding the patient's body is not allowed to escape. A cool, damp cloth should be kept constantly on the forehead to prevent headache or an uncomfortable sensation of fullness which might otherwise occur.

Bottles or rubber bags filled with hot water, placed close to the legs and body of the patient, are very serviceable; hot tub baths may be used, with great benefit, in the incipient stage. When available, the electric-light bath is the most natural, effective, and grateful means of applying external heat, as the patient at the same time receives the benefit of powerful light coupled with ozone.

External heat, as a means of inducing perspiration, is to be preferred to drugs; the latter always produce additional effects which it is better to avoid. In fact, the fewer the drugs that are employed in the treatment of this or any other disease, in order to secure desirable results, the better it is for the patient. His vitality is not wasted in maintaining activities which have no direct remedial bearing upon the disease. Encourage sleep. Avoid everything that has a tendency to startle or shock the patient, as noise, unnecessary conversation, touching him with cold hands; and see to it that his chest is not oppressed by heavy coverings or by weight or pressure from any cause, such as poultices.

Just here I desire to utter an emphatic protest against the use of very cold applications, especially in the form of ice, over the lungs. Instead of diminishing the internal congestion, as it is supposed to do, by drawing the excess of blood into the circulation, a very different result, according to Dr. Hensel, is produced. "Owing to the attempt to diminish the heat by ice, the congested blood," he says, "is by no means drawn into the general circulation, but because of the mechanical constriction of the capillaries, through cold, it is merely driven into the capillaries at a little distance from where the ice is placed. While the cold operates and the paralyzing action of the ice on the nerves continues, no evil effects are perceived, but as soon as the ice is removed the congested blood begins to decompose and poisons the rest of the blood in the body. Then we read in the papers: 'In spite of the fact that ice compresses were applied with frequency, the disease was, nevertheless, not overcome, and all the skill (?) of the physicians proved in vain.' The proper way of expressing this, he adds, would be "the inflammation of the lungs passed into putrefaction because the pedant of a doctor made the mistake of keeping the inflamed blood fixed in one place, by the application of ice, instead of conducting it towards the skin and so distributing it through the system."

Another very important adjunct of ozonation, and in some measure a substitute for it, is oxygen. How many physicians are there who use oxygen in the first stage of pneumonia? Yet, this is the very period in which it is capable of doing the most good. At this stage, oxidation of the morbid contents of the air-cells is more rapidly accomplished and normal circulation more readily reestablished than later, when solidification has occurred.

Elimination must be looked after. Keep all of the eliminative organs active. If the bowels are constipated, give a saline cathartic followed by olive oil as a lubricant and nutrient, and keep them open by at least two enemas daily. No more effete matter should be allowed in the colon than is absolutely unavoidable, so that danger from the absorption of toxins will be reduced to a minimum.

In the use of drugs my favorite prescriptions for an adult are: Tincture of aconite root, ½ to 1 drop, with tincture of veratrum viride, 1 to 2 drops, in water, every half hour or hour, until perspiration is well established; and asafetida, 5 to 10 grains, in capsule every four hours. The aconite opens the peripheral capillaries, and the veratrum gives the heart power to force the blood through them and also opens the larger vessels, thereby depleting the congestion in the lungs. This prescription should be discontinued when the crisis is reached, and strychnine, in small doses (1-100 to 1-60 grain), should be given three or four times a day, as the pulse may indicate. I seldom find the strychnine necessary when ozone is administered, because the latter is of itself a powerful stimulant.

The asafetida is a pulmonary and nerve stimulant, and the number of doses should be diminished to one or two daily, as soon as the lungs become free and clear. Parenthetically, I desire to state that I find asafetida, in large doses, to be of the greatest assistance in the treatment of all congestions and particularly of the lungs. It is a mild cathartic and diuretic and exerts a marked germicidal influence. Physicians who cannot avail themselves of ozonation will find it, as prescribed above, of paramount importance in all cases of pneumonia.

The patient should be well nourished in order that his strength may not wane. Maintain nutrition by all the appropriate food he can bear. Delicate persons with weak digestive power require food which is readily digested, such as milk and eggs, in small amounts, frequently repeated. After the crisis I often allow beef juice and hearty food. It is here, in the rôle of improving nutrition, that

ozonation plays such an important part. It seems to stimulate all of the nutritive processes throughout the entire digestive tract. Under its influence foods are digested and assimilated which otherwise the system could neither tolerate nor utilize. Stimulants are seldom needed when ozonation is employed. Otherwise, it is necessary to give them liberally, especially in the form of whiskey, when there is delirium or when the heart's action is weak.

After the lungs are clear, do not keep your patient constantly in bed, under the impression that the recumbent position will conserve his strength; too much inactivity always results in weakness. Let him sit up, more or less, the first day after the crisis. Unless he has organic heart disease, I have found nothing but the best results to follow this practice. Of course, if the patient has become exhausted by a prolonged illness before this specific treatment is resorted to, the recumbent position should be insisted upon; but as a general rule the more the patient is kept in bed the longer will be the period of his convalescence.

With the exception of ozonation, the different features comprised in the method I am advocating are neither new nor untried. They have been successfully employed by me for many years. But since I have been using ozonation my success has been phenomenal.

One word, in conclusion, concerning the advantages afforded by this method. In addition to the greatly lessened mortality, which is its best recommendation as well as a source of great comfort to the patient, it is highly appreciated by business men and those occupying positions of trust and responsibility on account of the speedy recovery it insures.

Moreover, because of the rapid and thorough elimination of the disease, owing to the invigorating methods employed, not only are many complications and sequelæ avoided, but chronic, minor affections from which the patient may have suffered often permanently disappear.

Preventive medicine is the ideal goal of medical science, and the more successful the physician is in preventing disease or curtailing its course the greater service does he render to humanity.

PRIMARY CARCINOMA OF THE INFERIOR TURBINATE, WITH REPORT OF A CASE.

By William Wesley Carter, A.M., M.D.,
New York.
Assistant Surgeon Manhattan Eye, Ear, and Throat Hospital.

Probably no more serious or important duty ever comes to the rhinologist than that of making an early diagnosis in cases of suspected malignant disease of the nose. The disease is insidious in its development, and experience here, as in other parts of the body concealed from direct inspection, shows that the diagnosis is seldom made early enough to eradicate the disease by operation, for the mortality is practically 100 per cent., which includes both operative and non-operative cases.

Malignant disease of the nose is very rare and usually occurs in the ethmoidal or sphenoidal region; the case that I present, therefore, is one of the rarest clinical developments of intranasal malignancy, for the disease is primary and in the lower part of the nose.

Mary C., aged thirty-eight, married, applied for treatment in the Manhattan Eye, Ear, and Throat Hospital early in October.

Her family history is good. She has always lived under fair hygienic conditions. Appetite and digestion are good, and the bowels are regular. She is a moderate tea and coffee drinker and takes beer occasionally.

Her menstruation began at sixteen, was regular until several years ago, since this time it occurs sometimes as often as every two weeks. She does not remember ever being sick except after miscarriage six years ago.

Her present illness began five months ago with a tickling sensation in the right nostril, and a constant desire to blow the nose. In a short time this was followed by spontaneous hemorrhages from this nostril; in four weeks the hemorrhages had greatly increased in frequency and the nostril was occluded. In the meanwhile she suffered continually with headache. At this stage she applied for treatment at a dispensary, where a growth was removed from the right nostril. This relieved the stenosis and other symptoms for the time. In four weeks all of the original symptoms had reappeared. She then went to a private physician, who removed the growth and examined it under the microscope. He found that it was cancerous and advised her to go to the hospital for more radical treatment.

I saw the patient three weeks after the last removal of the growth. The woman was well nourished, showed no signs of cachexia, and except for being extremely nervous seemed to be in good physical condition.

Examination of the nose showed a cauliflower-looking mass attached to the anterior extremity of the right inferior turbinate, and almost filling the nasal cavity; it evidently extended back some distance, but just how far could not be determined by anterior examination, and it could not be seen by posterior rhinoscopy. There was a serous, odorless discharge from the nostril and this, where it filled the sulci between the coarse granulations that covered the growth, had a milky appearance. Otherwise the nose and its accessory cavities seemed normal.

A large piece of the growth was removed with the snare for microscopical examination; this operation was followed by considerable hemorrhage. The tissue was very friable, offering no appreciable resistance to the snare. The specimen was examined by Dr. Jonathan Wright, who promptly stated that it was a typical columnar celled epithelioma. An immediate operation was advised. Believing that a cancer of five months' standing or longer must have so seriously involved the adjacent tissues and especially the antrum, that an excision of the superior maxilla would be necessary, the case was referred to a general surgeon.

On October 4 Dr. Andrew J. McCosh performed the following operation at the Presbyterian Hospital, the writer being present:

Fergusson's incision, reaching from the inner canthus of the right eye down by the side of the nose and through the middle of the upper lip, was made. All the tissues were elevated from the anterior wall of the antrum, and the soft tissues of the nose from the margin of the nasal cavity. The nose was then pulled toward the left, giving a good view of the operative field. It was then seen that the growth was confined to the inferior turbinate, and an opening into the antrum showed this cavity to be normal. The whole of the external wall of the nasal cavity down to and including a portion of the floor was removed, together with the inferior and middle turbinates and a large portion of the anterior wall

of the antrum. From an examination of the specimens removed the pathologist of the Presbyterian Hospital confirmed the diagnosis of cancer.

Though the growth involved only the anterior two-thirds of the inferior turbinate, the operation was extended far into the normal tissue, as was afterward shown by the microscopical examination of numerous specimens. We believe that every particle of malignant tissue was removed locally, for the operation extended far beyond the limits of probable invasion by contiguity.

The external wound was closed and drainage was effected through the nose. Primary union took place and the patient was discharged from the hospital on October 19, fifteen days after the operation.

She was put on tonic treatment and at present, nearly three months after the operation, she seems in better condition than when I first saw her. There are at present no signs of recurrence. A later report upon this point, however, will be of more value.

Points of special interest in this case are:

1—The extreme rarity of primary cancer of the nose, and especially of the inferior turbinate.

2—The early age at which the growth appeared (it being almost unheard of before the forty-fifth year).

3—The age, location, and extent of the growth seemingly being favorable, we have here a fair opportunity to test the efficiency of the radical operation to cure malignant disease of the nose.

The first case of primary cancer of the nose was reported by Robin in 1852. However, as late as 1869 no less accurate observers than Finder, and Cornil and Ranvier denied that malignant disease ever originated in the nose; and though this assumption has been proved to be incorrect, we may still state that its occurrence in the nose is very infrequent compared with other parts of the body.

Dreyfus, who considers only those cases in which there has been confirmation by the microscope, states that out of 9,554 malignant tumors of the entire body there were only 19 of the nose; of these 15 were sarcomata and 4 carcinomata.

In 28,000 patients seen by Herzfeld during a period of ten years, only one case of carcinoma of the nose was observed.

In Frankel's clinic Finder observed 10 sarcomata and 4 carcinomata among 28,000 patients.

Maljutin states that out of 125 malignant tumors of the nose collected by him only 17 were carcinomata.

In 1903 Darnall stated that the total number of reported cases of primary carcinoma of the nose and its accessory cavities was 79. All of these, however, were not confirmed by the microscope. A search of the literature since this time enables me to add to this number 19 cases, making the total number up to date 98. It seems almost necessary, if we consider these statistics, to classify primary malignant disease of the nasal cavities with that of the accessory sinuses, as many of the cases were seen only after the involvement of so much tissue that it was impossible to tell exactly where the growth originated. It is generally admitted, however, that primary malignant disease of the accessory sinuses is much more common than of the nose, and it is highly probable that a great majority of these 98 cases originated in the accessory cavities.

A review of the cases shows that sex has no appreciable influence in the etiology of the disease.

Carcinoma of the nose occurs only in later life, hardly ever before the forty-fifth year. Here carcinoma stands in strong contrast to sarcoma, which may occur at any age, but especially in the young; Schneigelw reports a case of chondrosarcoma of the nose in a child two years old.

By some, trauma is considered an etiological factor, but these men base their belief on such uncertain evidence as the statements of the patients as to when the trouble began, as in a case mentioned by Becker, whose patient attributed the disease to a fall on the back of the head. Irritated areas in the nose from which polypi have been removed have been spoken of as the seat of carcinoma. Cases demonstrating this origin have been mentioned by Trautman and Frick.

As to the origin of carcinoma from polypi, there has been much discussion. As yet, however, no stronger evidence has been brought forward to support this view than that of association. The fact that carcinoma most frequently occurs in the upper part of the nose in the region of the sphenoid and ethmoid, the area usually affected by polypi, certainly suggests some relation between the two. If, however, we take into consideration the frequency with which polypi are found, their occasional occurrence with carcinoma is to be expected. Heyman found that polypi constituted about 10 per cent. of all his nasal cases; and Zukerkandl found polypi in the nose in one out of every ten autopsies. At the same time we are not in a position to say that the irritating presence of polypi does not favor the development of carcinoma. In fact, long continued irritation in the nose, as in other parts of the body, seems to be a strong factor in the etiology. The polypi accompanying the cancer and sometimes combining with it, forming a mixed growth, may be accounted for by the irritation of the cancer and its necrotic products.

There is evidence that cancer may be developed from such benign growths as adenomata and papillomata after the cancerous age has been reached, and when they have been subjected to long-continued irritation. Kümmel, who made a microscopical study of the epithelial cancers of the nose, says that they all remind one of adenoma, and he believes this to be the chief origin of cancer. Cordes reported a case that seemed to be developed from adenoma. Polyak observed a pure papilloma for two and a half years that later showed cancerous metaplasia under the microscope. Citelli and Calamida also found microscopically that a papilloma that had been subjected to many irritations became cancerous. On the other hand, Sir Felix Semon says that he has not seen such transformation occur in 10,000 cases.

The disease is so insidious in its development that it may be far advanced before the symptoms are sufficiently pronounced to send the patient to the physician.

Nasal obstruction and headache are probably the earliest symptoms. Repeated hemorrhages may be mentioned as one of the earliest and most suggestive signs of malignancy; they may be spontaneous or induced by slight traumatism. In my case nasal stenosis, headache, and hemorrhage were the only subjective symptoms. Pain, at first neuralgic, later deep and boring in character, is a late symptom; it is present early if the growth is in the upper part of the nose.

The discharge may be serous, bloody, or purulent, and if the disease is advanced it has a necrotic, fetid odor. When the sinuses are involved, the early symptoms are those of empyema of these cavities.

Infiltration in carcinoma of the nose does not seem to be as rapid as in some other parts of the body. There is a tendency for the disease to extend upwards along the lymph channels that communicate with the subdural and subarachnoid spaces, many of the cases terminated from cerebral involvement. It also extends backward toward the choanæ and ptarygoid fossæ. Recurrence is very rapid after incomplete removal. In my case the growth had fully returned within four weeks on both occasions when it was removed to relieve stenosis.

There is little or no tendency to metastatic deposits in other organs. Glandular involvement does not occur so often, nor as early, as in malignant disease in other parts of the body. The lymph stream of the nose runs to the back of the choana and is collected in the side walls of the pharynx; here it communicates with one or two glands situated near the Eustachian tube. It then divides, one part courses downward and outward, joins the vessels from the tonsils and arches of the gums and communicates with the deep cervical glands, one part goes to one or two glands situated near the greater cornu of the hyoid bone. The second division passes backward and communicates with a gland situated in front of the axis vertebra. In only two of the recorded cases were the glands of the neck involved.

From an anatomical point of view the lateral pharyngeal gland, the gland in front of the axis, and the glands near the greater cornu of the hyoid would be the first involved in carcinoma of the nose.

Cachexia is one of the late symptoms; it was not present in my case.

In making the diagnosis we must differentiate from sarcoma, benign tumors, tuberculosis, and syphilis, also from chronic inflammatory conditions. The writer once saw a granular mass on the right middle turbinate of a man who had been accustomed to take snuff through his right nostril for many years. From its appearance it could have been mistaken for a malignant growth; it proved to be an overgrowth of tissue due to the irritation of the snuff.

Sarcoma differs from carcinoma in that it may occur in the very young; it is usually bluish-red in color and has considerably more consistency, in some cases being quite hard. It produces its deformity by pressure and displacement of normal structures rather than by ulceration, as in carcinoma, and it is not as a rule accompanied by cachexia.

Benign tumors usually have pedicles, while malignant ones are sessile.

There should be immediate cooperation between clinician and pathologist in suspicious cases, for an early diagnosis offers the only chance for successful operative interference. Where a diagnosis of cancer is made, the radical operation should be performed as soon as possible after the removal of the specimen for microscopical examination, lest this procedure should accelerate the disease. We must remember that this traumatism may not only liberate the cells of the cancer, which are very loosely bound together, but it may open up blood-vessels and lymphatics to take them up and disseminate them beyond the intended operative field. Cells thus taken up have been seen in the lymph channels under the microscope by several pathologists. That the fatal termination is greatly hastened by every inadequate operative procedure is borne out by the experience of every writer on this subject.

The prognosis is bad; only recently Bloodgood has stated that not one of the 18 patients with malignant disease of the nose operated upon at the Johns Hopkins Hospital recovered. There is no authentic case on record where recurrence has not taken place after the operation, and often this recurrence has taken place before the patient was able to leave the hospital.

The duration of the disease depends upon the age of the patient and the nature and location of the growth. The disease progresses more rapidly in the aged, and when it is located in the upper part of the nose. The medullary and adenocarcinomata are the least malignant and last the longest. The average duration of the disease is from one to three years. But Heurteux reported a case that lasted fourteen years, Bosworth one that lasted nine months, and Darnall and Gibb each reported one that lasted only seven months.

But one variety offers any ground for a favorable prognosis, and that is the so-called cylindroma of Billroth. However, there still remains among pathologists some doubt as to the malignancy of this growth.

Operative treatment alone is to be considered in dealing with these cases. If the site and extent of the lesion are favorable to complete removal, a radical operation should be done, otherwise all writers agree that a fatal issue is much hastened by interference. If, however, palliative measures are demanded for the comfort of the patient in inoperable cases, portions of the growth should be removed with the galvanocautery. The dangers of the operation are hemorrhage, pneumonia, erysipelas, sepsis, and meningitis.

The choice of operation should be made according to the location and extent of the growth, and with a view to giving access to the greatest amount of nasal tissue. Intranasal operations are useful only as palliative measures.

In some cases a modified Jansen's operation may be effective, but where the growth is in the upper part of the nose, and both sides are involved, perhaps Ollier's operation gives the best view of the field; this consists in sawing through the nasal bones and turning the nose forward on the face. When the antrum is involved, excision of the superior maxilla is the only operation to be considered.

60 West Fiftieth Street.

EMBOLISM.

By JOSEPH N. STUDY, M.D.,

CAMBRIDGE CITY, IND.

The name embolus applies to any foreign body floating in a blood-vessel. Before becoming detached these bodies are known as thrombi. One of the very frequent sources of embolism is a pathological condition of the inner coats of arteries, veins, and the cavities of the heart. An altered condition of the blood, in which its viscosity is possibly increased, following disease or other conditions, may at times have something to do in the formation of emboli. Upon either an acute or chronic phlebitis bacteria of various sorts and other matter may collect to form these bodies. It is not improbable that many cases of embolism occur from the direct entrance into the blood stream of elements capable of producing this condition.

An embolism may be septic or aseptic. The em-

boli may be small enough to pass through the smaller blood-vessels, or sufficiently large to completely obstruct the larger arteries, or even a cavity of the heart. A fat embolism sometimes follows trauma to the soft parts, where there exists adipose tissue, as well as in fractures where bone marrow is exposed, the fat globules finding their way into the circulation. Fat embolism has been detected in the brain and spinal cord. It has been thought that a fat globule, by being rapidly propelled against the sides of an artery, may be broken into smaller particles, reaching the floor of the fourth ventricle, where the cardiac and respiratory nerve centers are located, in this way causing sudden cessation of one or both of these organs. It is not improbable that many sudden deaths following diphtheria, pneumonia, and various other conditions, and usually attributed to heart failure, are due to infected septic emboli finding their way to the cardiac nerve centers.

All recognized authorities have in the past taught and emphasized the matter in no uncertain way of the danger of air entering a blood-vessel, and its liability to produce embolism. More recent experiments upon horses and the smaller animals teach that it is only when large quantities of air enter the circulation under considerable pressure that any serious symptoms arise. Then that air may enter a blood-vessel, either from a surgical operation or trauma, to a vessel in sufficient quantities to produce death, is rather improbable. It does seem very probable that metastatic abscesses in various organs and local inflammation, as well as ulcerated conditions, do at times owe their origin to infected emboli. Embolism has complicated and followed various pathological conditions. It has followed and complicated typhoid fever, pneumonia, diphtheria, childbirth. It is said very frequently to follow surgical operations, more especially within the pelvic cavity.

In the differential diagnosis of embolism, where trauma precedes this condition, there are three things to consider. Shock usually occurs within three hours, fat embolism three days, pulmonary embolism three weeks. Seventy per cent. of all emboli probably enter the pulmonary artery. As these bodies most usually originate in a vein, they enter the right side of the heart, consequently the pulmonary artery is a favorable site for their migration. The clinical history of many cases of embolism would indicate that this condition frequently occurs simultaneously with, or following some bodily movements, or excitement, as walking, laughing, or other muscular movements, which seem to aid in liberating these bodies; and when once detached evidently they soon reach their final destination. Embolism may terminate in one of three ways —in instant death, in delayed death, or in recovery. When the pulmonary artery is completely closed death must necessarily soon occur.

It is said that recovery has followed the complete obstruction of one of the primary branches of the pulmonary artery. An embolism is at all times a dangerous quantity to deal with, and as such must so be considered. However, even in the lungs emboli do not always produce death. The lung tissue being nourished by a separate set of vessels, the bronchial arteries, its nutrition need not necessarily suffer. Local inflammation that writers have described so often and termed as embolic pneumonia is very liable to follow the migration of an embolus into the lungs. Such a condition may terminate in various ways.

I desire to report two cases of pulmonary embolism.

Case I.—Mrs. W——, age thirty-one, American, married two years, was never pregnant; menstruation was regular but attended with some unusual pain at times. Her previous health had been good. She presented a most excellent physique, weighing about 140 pounds. She was taken with some pain, not severe, about the left ovary, and was having some little increase of temperature, not exceeding 100.5°. At the end of four days she had a normal temperature and was free from pain, and professional visits were then discontinued. The following afternoon she was up about the room and some neighboring ladies had called to see her, when she expressed herself as feeling quite comfortable. Soon after, she was in the act of walking across the room, when she experienced great difficulty in breathing, was assisted to a couch, and some thirty minutes later died. Through the courtesy of her physician, Dr. J. E. Wright, I was permitted to assist in making an autopsy, and was accorded the privilege of reporting the case. The pulmonary artery contained a spindle-shaped embolus one inch long, completely obstrucing the vessel, which was of a dark red color and of a friable consistence, easily breaking when manipulated between the fingers. The left Fallopian tube contained about one dram of a seropurulent fluid. No other pathological condition was observed.

Case II.—Mr. S., age forty, American, farmer by occupation, previous health good, sustained a fracture of the left patella, the lower fragment being broken into two pieces of about equal size. There was considerable ecchymosis over the knee, as well as swelling. The fracture was dressed in the extended position, and the patient had made satisfactory progress until the twenty-first day after receiving the injury. The man had eaten his breakfast and had read the morning papers, directed his hired man about his work, and expressed himself as feeling well. One hour later he was placed upon the commode for his bowels to move, and when being replaced upon the bed he experienced much difficulty in breathing. He was soon visited by his physician, Dr. A. E. Ehle, and his breathing and heart's action were so alarming that strychnine and one pint of normal saline solution, subcutaneously, were administered. The strychnine was repeated at intervals of two hours. Six hours after the beginning of the attack I visited the patient and noted the following conditions: Respirations 48, pulse 150, temperature in axilla 103.5°; skin somewhat cyanosed and perspiring freely; neither pain nor cough was present, but the patient complained of want of air. The stethoscope revealed air in normal quantities entering both lungs. The following forenoon I again examined the patient, when his respirations were 44, pulse 140, temperature 102.5°. No pain was complained of, but an occasional dry cough. Auscultation indicated that air in normal quantities was entering both lungs, and still he felt the need of more air. Four days later I examined the patient, when his respirations were 34, pulse 125, temperature 102°. Auscultation revealed partial solidification of the lower portion of the left lung. At no time was pain complained of, neither was there any expectoration. At the end of four weeks the man was permitted to sit up. Two months later the patient appeared at my office, the injured limb yet swollen up to the groin, supported by a rubber bandage. His lungs seemed to have fully recovered from the embolic obstruction.

REPORT OF A CASE OF INOPERABLE ROUND-CELLED SARCOMA OF THE OVARY;

SUCCESSFULLY TREATED BY THE MIXED TOXINS OF ERYSIPELAS AND BACILLUS PRODIGIOSUS, COMBINED LATER WITH OPERATION.

By HENRY C. COE, M.D., and WILLIAM B. COLEY, M.D.,

NEW YORK.

Mrs. E., aged thirty-two, wife of a lieutenant of the U. S. Army, was referred to Dr. Coe by Dr. H. Eugene Stafford of the Philippine Civil Hospital of Manila on December 29, 1904, under whose care she had previously been. Her previous history, as given by Dr. Stafford, is as follows:

Early in November, 1904, Dr. Bailey of the U.S.A. was called in to see the patient, and he treated her for two weeks for what he supposed was an inflammation of the left ovary, when a tumor developed and he referred her to Dr. Stafford for operation. Dr. Stafford saw her in consultation with Major E. C. Carter of the U.S.A. Examination revealed a large, immovable mass filling the pelvis. The uterus was crowded down almost to the external genitals. There was considerable tenderness of the lower abdomen, which did not permit of much palpation, and the abdominal muscles were rigid. She was prepared for operation and upon becoming anesthetized the abdominal muscles relaxed and the tumor was seen to have grown up to, and a little above, the umbilicus to the right side. Upon opening the abdomen the mesentery was found adherent to the outer surface of the tumor. This being dissected free and a portion incised, the tumor was seen to be nodulated in character, of a dark bluish-white color, and, upon passing the hand down its anterior surface to the pelvis, the greater portion was found adherent. Upon pulling the tumor forward enormous blood-vessels were seen, covering the back of it and springing from and above the posterior brim of the pelvis. From the general appearance, its rapid growth, and extreme vascularity, we decided it was a malignant growth, probably sarcomatous. On endeavoring to free the tumor from the blood-vessels, we found it was not adherent, but was growing apparently from the whole of the pelvic wall, and its bleeding so freely convinced us that it would be wisest to abandon further interference, particularly as her husband desired her to reach home to see her parents before dying. The incision was closed and the patient was more comfortable. A portion of the tumor was tied off and excised and sent to the Government laboratory. The pathological report, which convinces me that the patient will hardly live to reach New York, reads as follows: "An apparently rapidly growing and infiltrating, very cellular growth of probably perithelial origin; perithelial hemangiosarcoma."

The patient entered the General Memorial Hospital on February 20, 1905. At that time the physical examination revealed practically the same conditions as just described by Dr. Stafford. Her general health was steadily deteriorating and she was losing weight. Since the operation she had menstruated every twenty-eight days, the flow continuing for seven days, moderate in quantity. Heart and lungs normal. Inasmuch as the tumor was firmly fixed and clearly inoperable, Dr. Coe turned the case over to Dr. Coley for treatment with the mixed toxins, which was begun on February 24, 1905, the first dose being ½ minim, which was injected into the abdominal wall. The injections were continued three to four times a week, in gradually increasing doses up to the point of producing a moderate reaction, a temperature of 101° to 102°. The patient's general condition was not such as to permit of giving her very large doses, and often a temperature of 102° was followed by a good deal of depression; the highest dose reached was 7 minims and the highest temperature 104.8°, which occurred on March 30, following an injection of 6 minims. Most of the reactions were much less severe, the temperature usually not rising beyond 101°. She received in all forty-seven injections, the last being given May 31. The *x*-ray was given in combination with the toxins, though much less frequently, the patient receiving all told twenty-two exposures of an average duration of ten minutes. There was a very slow diminution in the size of the tumor during the period of treatment and marked increase in its mobility. Her general condition showed no improvement—in fact, it seemed there was slight deterioration. It was clearly evident that her condition would not permit of giving large enough doses to produce complete absorption of the tumor, and in view of the marked increase of mobility we decided, after careful examination, that there was a possibility of removing the tumor by operation.

On June 12, 1905, operation was performed by Dr. Coe, assisted by Dr. Coley. A tumor, about the size of a child's head, was found, originating in the right ovary, markedly pedunculated and almost entirely free from adhesions. No metastases were present in the other organs. The pedicle was tied off and the tumor was easily and rapidly removed, the entire operation taking not more than fifteen minutes.

The effects of the toxin treatment upon the tumor were most remarkable, as shown by Dr. Martha Tracy's report, confirmed by Dr. James Ewing: "The tumor within was very much degenerated, the contents being almost of a puriform consistence. Therefore, it was difficult to fix and stain, and the diagnosis is not clear. Dr. Ewing is unwilling to say whether it is sarcoma, endothelioma, or carcinoma, though of the malignancy there is no doubt." The report of a less degenerated portion of the tumor by Dr. Clark, the pathologist to the General Memorial Hospital, was round-celled sarcoma.

The patient made an uninterrupted recovery, gained twenty-eight pounds in weight during the next six weeks, and returned to her home in perfect health. Within the next six months she conceived and gave birth to a healthy child in the summer of 1906. She remained well up to the latter part of January, 1907, when she contracted pneumonia and died within a few days.

The case is interesting from several standpoints. First, because sarcoma of the ovary is an exceedingly malignant neoplasm. We have never yet seen a case cured by operation. Second, because the tumor, though clearly absolutely inoperable at the start, became operable by the preliminary treatment with the toxins, possibly assisted by the *x*-rays, although we have never had an abdominal sarcoma show much improvement from the *x*-rays alone.

While sufficient time had not elapsed to warrant us in classing the case as cured, the complete restoration to health and prolongation of life for nearly two years, when it was cut short by an attack of pneumonia, make the case of sufficient interest to merit reporting.

Note.—From a recent letter received since the above went to press, there seems a possibility that there was metastases in the lung instead of a typical pneumonia.

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

THOMAS L. STEDMAN, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51 FIFTH AVENUE.

New York, March 16, 1907.

ESPERANTO.

AMONG the countless attempts that have been made to construct an international language to serve as a common means of communication for all the peoples of the earth, Esperanto stands out as the most successful. Volapük seemed at one time about to conquer the world, but the movement went to pieces by reason of certain fatal defects in construction and of the obstinacy of the creator of the language in refusing to accept any amendments looking to the correction of these faults. Dr. Zamenhof, the originator of Esperanto, is, however, a different sort of man, whose modesty and whose love for the creature of his brain forbid that he should destroy this by refusing to listen to proposals for its betterment, if such might be found necessary. But, so perfect is the instrument his genius has created, that there is apparently no room for any but the most trivial changes. It is unnecessary, even if space permitted, to describe the mode of construction of the language, for those interested can readily obtain authorized grammars which can be mastered in a few days of careful study. It is a language of root-words, most of which are already familiar to anyone with a reading knowledge of the three principal tongues of Europe. From these roots, by means of prefixes and suffixes, is built up a vocabulary which seems to meet every verbal need of man, whether for ordinary conversation or for scientific discussion. Anyone of average intelligence can master these rules of construction thoroughly in one week by giving an hour a day to their study. Then, if already familiar with Latin and Teutonic roots, he will be able to read almost at sight any Esperanto text, using a dictionary only to learn the meaning of the few Slavonic roots that Dr. Zamenhof, himself a native of Bielystok, Russia, has incorporated in the language. The ability to write or speak the language would, of course, demand more practice, but the diligent student would in a month find himself able to communicate with ease with Esperantists in any part of the world—at least, so the Esperanto enthusiasts claim.

It will surprise those who have not had their attention turned to the subject to learn what a position this new language has already acquired in the few years it has been in existence. Mr. Joseph Rhodes, vice-president of the British Esperanto Association, says (we quote from the *North American Review* of February 15, 1907): "Statistically considered, up to June, 1906, Esperanto was known to have penetrated to 31 countries, and 377 societies or groups were at work, Europe being credited with 349, America with 16—the United States having then 10 societies in 7 centers—Asia with 7, Africa with 3, and Oceanica with 2. To give a census of Esperantists is impossible, but a recent moderate guess at their number is 300,000. There are also 31 professional societies or organizations using Esperanto for special objects, 28 Esperanto magazines, in which the national language appears side by side with the international, and 8 national periodicals containing a regular Esperanto column. Europe is, so far, the center of gravity, and here the societies are distributed: France, 94; Great Britain, 64; Germany, 35; Austria-Hungary, 28; Switzerland, 22; Russia and Spain, 21 each; Bulgaria and Sweden, 15 each; Belgium, 14; Holland, 7; Denmark and Malta, 3 each; and Monaco, 1."

Any movement, whether linguistic, socialistic, religious, or scientific, which has acquired such a momentum in a single lustrum (Dr. Zamenhof's first pamphlet was put forth in 1887, but, though a few enthusiastic recruits were obtained almost immediately, the language has really been launched but little more than five years) is worthy the respectful attention of thinking men. It is already receiving practical recognition in many of the countries of Europe. The governments of France and Belgium are considering the advisability of teaching Esperanto in the public schools; the London County Council has authorized the study in some of its schools; it is being taught unofficially in the French Army; the London Chamber of Commerce has placed it among the official subjects of examination; the children of many of the royal families of Europe are learning it; and in Germany there are two publishing houses making a specialty of Esperanto publications. Medical men, especially in France, but not a few in this country, are enthusiastic students and propagandists of the language, and there is already in existence one Esperanto medical journal.

The need of an international language for scientists and physicians is self-evident, and the MEDICAL RECORD has repeatedly called attention to this, especially in relation to the Triennial International Medical Congress, in which the babel of tongues is so manifestly a bar to intelligent discussion. The immense advantage that there would be in the use of a single language, understood and spoken by all in these congresses, is universally acknowledged, but unfortunately international jealousies stand in the way of the adoption of English, French, or German as the sole official language. The MEDICAL RECORD has from time to time urged the adoption of modern Greek (a language as easy to learn as French or German) as one which all might accept, without wound to national pride, and we still maintain, for many reasons which we cannot here repeat, that this would solve the problem satisfactorily, at the same time promoting sound scholarship. But, needless to say, the suggestion has failed of acceptance, and we frankly despair of ever hearing the melodious phrases of Hippocrates or Galen resound in the meeting hall of any international medical congress. It remains to ask whether Esperanto will supply this want of a means of international communication among medical men. It may, and we doubt not the question will be seriously considered at the

forthcoming Budapest Congress. Except as a compromise, we cannot imagine any scientific body adopting as its official tongue a Frankenstein creation—perfect indeed in form, but soulless, such as is Esperanto. Nevertheless, the need of some common means of communication is imperative, and the acceptance of any single language, even an artificial one, as the official tongue of those taking part in the discussions at international congresses would be of incalculable service to scientific progress.

SEQUESTRATION ANEMIA IN SURGICAL OPERATIONS ON THE BRAIN AND SKULL.

Hemorrhage must be regarded as the chief source of shock in operative work, and the efforts to check the same have always constituted one of the principle aims of surgical technique. The hemostatic clamp and ligature have been found wanting in many respects, and in certain operations, as on the limbs, the blood has been kept from freely circulating in the member by the application of an appropriate tourniquet. The value of this procedure is undoubted, for not only is the operative field kept clear, but the blood is stored away in other parts for use as a preventive of shock. But what surgeon, asks Dr. Dawbarn, in an article in the *Annals of Surgery* for February, 1907, when about to operate on however vascular a field of the head, the neck, or the body, ever applies this same principle, and, to avoid hemorrhage, accumulates blood in the extremities? The suggestion seems reasonable enough, and if it is advisable in one instance it is obviously so in the other. Naturally the extremities can be made more bloodless than other portions of the body, but Dawbarn claims that experience has shown that we can with entire safety withdraw into the limbs some quarts of the whole bulk of the blood, which constitutes one-thirteenth of the individual's weight. This temporary bleeding into the patient's own vessels can be controlled to a degree by carefully watching the pulse, and the sequestration can be continued until there is a noticeable softening and decrease in the tension, at which point the operation may be begun. In the cases in which the procedure has been applied the writer has observed not only a lessened degree of hemorrhage but also a diminished amount of surgical shock.

It would seem that the suggestion in question might with greatest advantage be applied in surgical operations on the brain or the skull, and Dawbarn has used the method in seven cases of this character. This has afforded a limited though sufficient experience to permit of drawing some conclusions as to its advantages and disadvantages, for it is by no means universally safe or applicable. To begin with, shock is apparently not threatened by sequestration anemia, although the brain and heart may temporarily be deprived of a considerable part of its blood. The vasotonic centers are still sufficiently supplied with the circulating medium, and the partial anemia is well borne compared with the loss of considerable blood, and so constitutes the lesser of two evils. Thrombosis and embolism are the two accidents to be most guarded against, and the causes which might operate to produce clotting of the comparatively quiescent blood are three: changes in the blood itself, in the vessel walls, and in the speed of the current. Normal blood will not coagulate even when the current is markedly slowed, as is evidenced by Bier's method of treatment, but if either the blood or the vessels are unhealthy, the predisposing cause is present which makes clotting possible and sequestration dangerous because of venous thrombosis and possible subsequent pulmonary embolism. Among the conditions which would serve as contraindications on this account are the recent occurrence of typhoid fever or puerperal sepsis, chlorosis or severe anemias of any kind, and the presence of lime salts in excess or atheroma of the vessel walls.

Among the chief advantages claimed for this method of sequestration anemia in brain and skull surgery, as summarized by Dawbarn, are the following: Ease of control of hemorrhage during the operation because of the lessened vascular tension; a shortened operation because of a dryer field; a lessened danger of sudden death from pressure on the respiratory center during work on a brain tumor or similar condition, because there is an accumulation of blood elsewhere, and finally more space between brain and skull for working, which permits the removal of old clots or the separation of adhesions without the risk of lacerating the surface of the brain. One feature about this procedure which needs comment is the fact that should any adverse indications appear during the course of the operation, such as irregular or rapid pulse, it is a simple matter to deal with it by slowly releasing one or more tourniquets, so that an increased supply of blood is afforded to the heart. Weighing the advantages and disadvantages of this procedure against the production of shock and hemorrhage, it would appear that the suggestion is a most valuable one if used with the due and proper precautions enumerated in the writer's paper.

THE EFFECT OF A SALT-FREE DIET IN BRADYCARDIA.

It has been observed in a number of instances that the complete withdrawal of salt from the food resulted in a return to the normal of a permanently slow pulse. Notwithstanding this fact, the knowledge has rarely been applied, because the condition of bradycardia has usually been attributed to some disturbance in the innervation of the heart or to a myocarditis, and treated accordingly, whereas in reality a chronic nephritis is almost always the cause of the trouble. Enriquez and Ambard (*Semaine Médicale*, No. 4, 1907), who have made a practical study of the subject, report one case in which the pulse increased from 32 to 72 beats within a period of seven weeks without any measures other than the withdrawal of salt from the food. At the same time there was a well-marked increase in the body weight. In seeking for a cause for bradycardia, the writers contend that as in a true case the contractions of the ventricle alone are diminished while those of the auricle remain normal in frequency, the innervation of the organ is not at fault, for muscular exertion will affect the contractions of both chambers. The other theory is based on the assumption that the motor impulse in a cardiac contraction affects the myocardium without the medium of the

intracardiac nerves. The connection between auricles and ventricles is represented by a muscle bundle which extends from the right auricle through the septum to the papillary muscles of the ventricles. Division of this bundle leads at once to a disturbance of the synchronism between auricles and ventricles. In the animals used for the experiments the procedure also produced the picture of a permanent bradycardia, and a compression of the bundle referred to resulted in the production of the well-known Stokes-Adams symptom complex.

Thus far eight autopsies have been recorded in cases of bradycardia in which the muscle bundle known by His' name has been found to be the seat of lesions, and this fact may be taken to constitute an important support for the myogenous theory of the disease. The reason why the withdrawal of sodium chloride is effective in such cases, therefore, becomes plain, for a chronic nephritis is usually present, together with retention of the chlorides, and the myocardium is therefore constantly bathed in a hypertonic solution which interferes with its proper functions. By withdrawing the salt, the correct physiological tone of the muscle is restored. An important point, however, is that a salt-free diet must be persisted in for a long period of time before any effect can be noted.

Cardiac Dilatation in Pneumonia.

The sudden death in this city not long since of a man prominent in the theatrical world called attention to the danger of a dilated heart in pneumonia. He had been ill for several days with pneumonia, but the attack was light, and recovery would doubtless have occurred had not acute dilatation of the heart occurred. That this is one of the most frequent causes of death in this disease has long been recognized, and not a few clinicians have believed that herein lies the sole danger of pneumonia, and have based their treatment of the disease upon this theory, their efforts being directed from the beginning of the attack to support of the heart. In the *American Journal of the Medical Sciences* for February, Beverley Robinson devotes a considerable part of an interesting article on "Acute Cardiac Dilatation" to the dilatation of the right side of the heart occurring in the course of pneumonia. He refers to the recommendation by A. H. Smith of immediate recourse to the vasodilators in such cases, since the indication is to shift the mass of blood from the veins when it is stagnating to the arteries and the left side of the heart. Robinson, however, believes that local bloodletting by leeches or wet cups is of greater efficacy, and he prefers this even to venesection. He believes the good effect is to be explained, not by the amount of blood taken from the patient, but by the reflex started locally in the right ventricle that is transmitted to the respiratory center, and from there becomes additionally stimulating to the heart. It is also true, as noted by Lees, that the vasomotor nerves are called into action through this reflex, and afford relief through dilatation of the peripheral arteries. We should beware of the use of digitalis instead of the vasodilators in these cases, though Robinson says that, after distention of the right heart has been relieved by leeches or venesection, digitalis may become very serviceable in giving strength to cardiac beats when the pulse is weak, rapid, and intermittent. Digitalis is also sometimes useful, in his judgment, when the heart as a whole is affected and weakened by the toxemia of pneumonia—not merely its right auricle and ventricle because of the pulmonary obstruction.

A Method of Identifying Tuberculous Pus.

About a year ago Müller and Jochmann described a method for determining the proteolytic power of specimens of pus by estimating the degree of digestion of coagulated blood serum caused by the presence of small amounts of the material to be tested. In order to do this, by means of a platinum loop or a glass rod, small drops of the pus are transferred to the surface of a Petrie dish containing Löffler's blood serum. The dish is then kept for a considerable length of time, preferably twenty-four hours, in an incubator maintained at the temperature of 50°-55° C. The occurrence of proteolytic ferment action is then shown by the formation of minute saucer-shaped depressions, of which the pus droplet forms the center. If no ferment is present in the pus the drop simply dries without causing any change in the surface of the medium. The proteolytic action was ascribed by the authors to the setting free of a ferment from the polynuclear leucocytes, and as one of their conclusions they suggested that it might be found possible to make use of this method in differentiating tuberculous pus from that produced through the agency of other microorganisms, owing to the fact that under the conditions stated proteolysis was not, as a rule, produced by tuberculous pus. This idea has been tested in a large number of tuberculous and nontuberculous cases by Kolaczek and Müller (*Deutsche medizinische Wochenschrift*, February 15, 1907). These authors have found that in dealing with pus coming from untreated, closed, purely tuberculous processes no proteolytic action on the blood serum was obtained, while, on the other hand, pus taken from other infections of the most varied nature never failed to give the characteristic digestion of the serum medium. It therefore appears that if a given specimen of pus does not exhibit any proteolytic powers the case is one of tuberculous nature, whereas if there is well marked digestion of the medium the process is probably one of an acute inflammatory character. The test is not, however, in its practical application as simple as this might seem to indicate, for in cases in which there is a mixed infection, or in which the condition has undergone treatment, particularly if this has taken the form of injections of iodoform, proteolytic powers of considerable activity may be present in the pus. Like many diagnostic tests the method, therefore, has a much greater negative than positive value, but it is quite possible that in the hands of those who have become familiar with its limitations it may prove of service.

The Treatment of Gonorrhea.

The multiplication of the remedies available in the treatment of specific urethritis has led to what is perhaps an exaggerated idea of the part played by local applications in the management of the disease. At any rate, Zieler (*Münchener medizinische Wochenschrift*, February 12, 1907) is of the opinion that in considering the therapeutic problems of gonorrhea one important factor is often lost sight of, or at least is not accorded the importance it deserves. This is the beneficial action of the inflammatory process itself, by means of which the bacteria in the deeper layers of the mucous mem-

brane, where they are more or less out of reach of even those urethral medicaments that have the greatest penetrating power, partly are destroyed by the bactericidal properties of the serum, and partly are brought up to the surface with the exudate. It is largely the virtue of the modern silver preparations that they encourage this favorable condition of local hyperemia and exudation without any attending damage to the tissues, while at the same time, through their antiseptic power, they destroy the gonococci that have been brought to the surface of the mucosa, and which would otherwise be able to proliferate actively in the exudate. While there is nothing essentially new in this doctrine it emphasizes a phase of the phenomena going on in the course of an acute urethral infection that is often disregarded, but which, in view of the modern tendency to attach more and more importance to the inflammatory reactions as salutary processes, must not be overlooked.

An Aid in Eliciting the Knee Jerk.

Clinicians not infrequently encounter difficulty in testing the knee jerks owing to the inability of the patient to relax properly the musculature of the leg under investigation. It was to facilitate the examination in such cases that Jendrassik devised his simple maneuver for diverting the attention of the patient, and thereby eliminating all stimuli that might interfere with the completion of the reflex arc. As is well known, this maneuver consists in having the patient pull, with the flexed fingers of the one hand against those of the other, at the same time looking upward. Krönig (*Berliner klinische Wochenschrift*, October 29, 1906) says that while this procedure is usually successful, it is sometimes difficult to induce patients of a low grade of intelligence, or children, to carry it out properly. He suggests in such cases resort to the following method: The patient is directed, at the word of command, as quickly as possible to take a forcible inspiration, at the same time looking upward. The patellar tendon is tapped while the patient is carrying out the prescribed act, and it is stated that the diversion of attention thus produced is sufficient to abolish all inhibitory stimuli. Krönig says that the measure is so simple that no difficulty is experienced in having patients of any sort put it into execution, and, after trying it in some hundreds of cases, he avers that it is just as effective as the Jendrassik maneuver, and is superior to this in its universal applicability. The method would seem to have the drawback of requiring considerable attention on the part of the examiner in order to time the percussion stroke properly, and we presume that in most cases the Jendrassik method will continue to be generally used. When difficulty is experienced with this it is possible that recourse to Krönig's suggestion may prove of service.

Autointoxication Following Laparotomy.

Intestinal paralysis after abdominal section occurs so frequently that it is accepted by many as a natural accompaniment of an operative invasion of the peritoneal cavity. Various causes have been assigned to account for this complication, among which damage to the gut by handling or exposure, sepsis, and peritonitis have been accepted as the most common and likely. Within two or three days after operation evidences of intestinal obstruction appear, such as meteorism, absolute constipation, nausea, vomiting, small rapid pulse, and a subnormal or slightly elevated temperature—a clinical picture familiar to most surgeons. If the patient dies the autopsy may fail to disclose evidences of either sepsis or peritonitis and nothing is apparently found to account for the often unexpected fatal ending. Dr. Keller of Berlin, writing in the *Zeitschrift für Geburtshilfe und Gynäkologie*, Vol. 55, No. 2, suggests that this form of intestinal paralysis may possibly be due to an autointoxication and reports two instances in which this seems to have been proven. In neither did the intestine receive any injury during the operation, and yet all the usual clinical symptoms of intestinal paralysis were present. The foul stools which followed the administration of a cathartic brought about a relief from the symptoms and the urine showed a large amount of indican. As a previous history of marked constipation was elicited in both of these patients it would be the part of wisdom, in every case intended for abdominal section, carefully to correct this faulty condition. Aside from the anteoperative prophylaxis it is advisable in every doubtful case to stimulate peristaltic action after operation by appropriate means, among which diet and the omission of opium are important factors.

Amyl Nitrite in Hemoptysis.

In the *Lancet* of January 19, 1907, Dr. Francis Hare refers to the recent publication of Abrams of San Francisco relative to the latter's statement that nitrite of amyl promotes hemostasis of the lung largely through reflex action. Commenting on this statement Hare maintains that the only physiological action of the remedy which rests on any secure foundation is the sudden production of vasodilatation, or in other words, the sudden inhibition of vascular tone, in wide areas, if not generally; this being of necessity associated with a fall of blood pressure and a compensatory acceleration of the heart beat. All other actions ascribed to the drug would appear to depend on mere inference from preconceived theories. For example, from the relief sometimes afforded by it in the asthmatic paroxysm, amyl nitrite is inferred to have the power of relaxing the bronchial muscles. But the inference is unjustifiable because the view that asthma depends on bronchial constriction remains an unverified hypothesis. The only view of the mechanism of the asthmatic paroxysm which is consistent with the known physiological action of amyl nitrite is the vasomotor hypothesis; amyl nitrite relieves asthma by relaxing the peripheral vasoconstriction, which is an essential factor in the bronchial vascular distention responsible for the obstruction to respiration.

News of the Week.

The Evil Spirit of Paternalism in Medical Organizations.—In his presidential address to the Medical Society of the State of New York, at its recent annual meeting, Dr. Joseph D. Bryant, now president-elect of the American Medical Association, said: "It would be sadly amiss, indeed, were I not to admonish you at the opening of a united career of the grave perils begotten by the spirit of paternalism which, not infrequently, is a pernicious by-product of organized power. The seductive and oppressive influence of this spirit often usurps, and may inhibit that nobler, more enduring, and beneficent one, characteristic of common manhood and of professional brotherhood. In this relation it

should not be forgotten that the greater and more extended is the membership of a fraternal body, the greater and more extended its constituent paternal desires are apt to be."

New York Skin and Cancer Hospital.—The governors of the New York Skin and Cancer Hospital, Second avenue, corner Nineteenth street, announce that Dr. L. Duncan Bulkley will close his clinical course with four special lectures as follows: March 27, "Practical Points in the Diagnosis and Treatment of Diseases of the Skin;" April 3, "Errors in Diagnosis and Treatment: Donts in Dermatology;" April 10, "Danger Signals from the Skin;" April 17, "The Significance and Treatment of Itching." They also announce a lecture by Dr. William Seaman Bainbridge on April 24 on "Some Phases of the Cancer Problem." The lectures, which are free to the medical profession, will be held in the Out-Patient Hall of the hospital at 4:15 o'clock.

Magazine for the Blind.—The first number of the *Matilda Ziegler Magazine for the Blind*, which has been established by Mrs. Matilda Ziegler, appeared last week. The magazine contains 96 pages and measures 14x12x2 inches. An edition of 7,000 was prepared, and nearly all the numbers have been sent out free, though the nominal price of the magazine is ten cents a copy. The number is made up of articles on a wide range of subjects, and a map of the West Indies and Central America, showing the situation of Kingston and of the Panama Canal, is included. The magazine is printed partly in New York point and partly in Braille point. The secretary of the New York Association for the Blind, Miss Winifred Holt, has announced that the association is in need of funds for running expenses, and that it is impossible on this account to give assistance to the large numbers of blind persons who are anxious to learn of some way of supporting themselves. The treasurer of the organization is Mr. Herbert S. Barnes, of 35 Wall street.

Hudson River Ice.—The report of the chemist employed by the Merchants' Association of this city to examine the quality of the ice being harvested from the Hudson shows that there was considerable evidence of sewage pollution in the samples analyzed. Of twenty-five specimens examined eleven are reported as "good," ten as "contaminated," and four as "bad." It must be remembered, however, that while it is undoubtedly highly undesirable that ice intended for domestic uses should be taken from sources open to suspicion or worse, if these analyses had been made in samples taken from ice that had been in storage for some months, as far as the bacteria are concerned, the results would probably have been much less unfavorable.

Compulsory Vaccination.—A bill has been introduced into the Pennsylvania Legislature requiring all children to be vaccinated before they are two years old, and also providing that persons taking up their residence in the State shall be vaccinated within one month or produce a physician's certificate that they have been vaccinated or have already had smallpox. It is further provided that any child or person required to be vaccinated under the provisions of this act, but suffering from any affection or condition that would as a result of vaccination become dangerous to life or health, may be excused from the enforcement of the law for a period of one year on presentation of a written certificate to this effect signed by a regularly licensed physician and indorsed by a physician appointed by the Department of Public Health or by any local Board of Health of the Commonwealth.

Illinois State University Medical School.—In 1897 the State University of Illinois organized a medical school as one of its departments. Not owning suitable buildings, it rented the premises of the College of Physicians and Surgeons, making an agreement with the college that the expenses of the new department, including rent, were not to exceed the fees received from the students. This agreement has been kept until the present, and the State has not contributed a dollar to the school, which has been supported by fees from its students. The development of the University has reached the stage where the ownership of its medical department buildings is necessary. The bill now before the legislature, while asking for an appropriation of $386,000, states that it is for the purpose of acquiring suitable buildings and equipment for the conduct of the medical department, and that in case the trustees should see fit to purchase the property of the College of Physicians and Surgeons, they shall not pay a sum to exceed the actual value of the tangible property.

Health Matters in Chicago.—Up to the close of February a total of 48,155 children in attendance on the public schools had been examined. Of these, 7,205, or nearly 15 in every 100, were either suffering, or convalescent, from a contagious disease, and capable of spreading contagion among other scholars. There were found 2,049 cases of diphtheria and tonsillitis, 695 cases of mumps, 686 of scarlet fever, 537 of measles, 228 of whooping-cough, 198 of chickenpox, and 2,812 cases of purulent ophthalmia, impetigo contagiosa, scabies, pediculosis, etc. Nearly one-third of the total exclusions were on account of diphtheria and tonsillitis, and nearly one-tenth were on account of scarlet fever. The Health Department asks, Is it any wonder that these diseases have been epidemic? Had medical school inspection been established and continued, as repeatedly prayed for by the Department, it might not have wholly prevented the scarlet fever epidemic, since the growing infrequency of this disease since 1902 had resulted in the accumulation of an enormous crop of children susceptible to its infection. An epidemic among these was inevitable whenever the specific contagion, whatever it may be, should be introduced. But there is no question among sanitarians and students of preventive medicine that its ravages could have been greatly reduced and its spread effectually checked had the early cases been promptly recognized and measures of restriction duly enforced.

The Inspection of School Children.—The Committee on Public Health and Legislation of the St. Louis Medical Society appeared before the Sanitary Committee of the City Council on February 26, together with representatives of other organized medical bodies, and argued in favor of the passage of a bill for the medical inspection of public school children. They report that the passage of the bill is practically assured.

Spectacles for School Children.—The managers of the New York Throat, Nose, and Lung Hospital have issued a circular addressed to school principals in Manhattan and the Bronx announcing that the hospital will hereafter supply spectacles free to school children whose parents are too poor to buy them, and also calling attention to the dental clinic of the hospital, where the teeth of school children will be treated free of charge. The dental clinic was established in October, 1905.

Throat Affections in School Children.—The school physicians of South Manchester, Conn., re-

cently found that 200 out of 1,000 public school children in that city were suffering from enlarged tonsils or adenoids to a degree that made operation advisable.

The St. Louis Medical Society has built a new auditorium and created fresh enthusiasm in its members. Many new members are being elected at each meeting, and the average attendance at the weekly meetings for the first two months of the year has been 129.

The Cincinnati Academy of Medicine celebrated its semicentennial at the Hotel Sinton on March 5 with a banquet, at which 350 medical men sat down. Dr. J. E. Greiwe, the retiring president, was toastmaster, and speeches were made by Drs. Byron Stanton, the only charter member present; Dr. A. G. Drury, Dr. N. P. Dandridge, Dr. P. S. Connor, Dr. B. P. Good, Dr. S. Nickles, Dr. C. D. Palmer, and Governor Bradley of Kentucky. The election of officers for the following year resulted as follows: *President*, Dr. F. W. Langdon; *First Vice-President*, Dr. Wm. Gillespie; *Second Vice-President*, Dr. John Oliver; *Secretary*, Dr. Mary K. Isham; *Treasurer*, Dr. A. G. Drury.

Berlin's Municipal Physicians.—The assistant physicians in the various municipal hospitals of Berlin have agreed to hand in their resignations on April 1. This is in order to express their dissatisfaction at the reply to a petition handed to the authorities over eight months ago. The petitioners asked that the salary of the official assistant hospital physicians be raised from 100 to 120 marks a month, that a yearly vacation of four weeks be granted, and that they be received into the Government accident insurance system. After eight months of delay a negative decision was rendered. Each assistant physician has seventy or more patients under his care and is on duty from 9 A.M. to 7 P.M. In the evening he has to write up the case histories. It is expected that the contemplated move of the physicians will cause the authorities to reconsider their decision.

Information Bureau in Berlin.—In the Kaiserin Friedrich-Haus an information bureau has been opened for the benefit of foreign medical students and physicians. It is the object of the bureau to supply free of charge information in regard to courses, hospitals, collections, and other matters of interest to visiting medical men.

Plague in Russia.—Dr. Schreiber, the worker in the Alexander Laboratory in Kronstadt, who contracted plague from cultures with which he was experimenting, has died, and one of his colleagues is reported to be suffering from a suspicious infection.

Smallpox is reported to be epidemic at Dunkirk, France, and also in Lille.

The Fourteenth International Congress for Hygiene and Demography will be held in Berlin, Germany, September 23 to 29 of the current year. The secretary-general of the congress is Dr. Nietner, Eichhornstrasse 9, Berlin W., to whom all communications with reference to the congress should be addressed.

Congress of the German Urological Society.—The first congress of this organization is to be held in Vienna, October 2 to 5, 1907. The principal theories for discussion will be the diagnosis and treatment of renal tumors, the diagnosis and treatment of nephrolithiasis and albuminuria. One of the features of the congress will be an exhibition of specimens and instruments pertaining to genitourinary surgery. Non-members of the society who wish to take part in the proceedings are requested to communicate with Dr. Kapsammer, IX. Maria Theresienstrasse 3, Vienna.

International Congress of Psychiatry, Neurology, and the Care of the Insane.—A congress for those interested in these matters is being organized under the auspices of the Dutch Society of Psychiatry and Neurology, to be held at Amsterdam from September 2 to 9, 1907. Those who have been invited to be American members of the committee of arrangements are: Dr. G. Alden Blumer of Providence; Drs. Charles K. Mills, John K. Mitchell and S. Weir Mitchell, of Philadelphia, and Dr. R. G. Rabinovitch, of New York City.

Seventh International Congress of Physiology.—This will be held this year at Heidelberg from August 13 to 16, under the presidency of Professor August Kossel. In connection with the congress there will be an exhibition of scientific apparatus. Announcements of communications should be sent to the Physiological Institute, Heidelberg, before June 15.

State Medical College for Oklahoma City.—A charter has been granted to a new regular medical college in Oklahoma City with the title of the Oklahoma State Medical College. The incorporators include Dr. W. J. Darnell of Mountain View, Okla., who has been made President of the school; Dr. West Moreland, Atlanta, Ga.; Dr. H. H. Baty of Rome, Ga.; Dr. J. R. Phelan of Oklahoma City, Secretary of the corporation, and J. P. Eckers of Oklahoma City.

City Hospital Buildings.—Plans have been filed for a group of new administration buildings to be erected on Blackwell's Island as annexes to the present City Hospital. The group includes two one-story reception houses for patients to cost $25,000 each, an operating pavilion to cost $25,000, a three-story kitchen and service building to cost $12,000, a three-story and attic residence for the medical staff to cost $54,000 and to be called Janeway Hall, and a two-story and attic residence for the hospital superintendent to cost $20,000. Plans have also been filed for two new recreation pavilions to be built on the island for the inmates of the City Home for the Aged and Infirm.

For Poor Tuberculous Patients.—A bill has been introduced into the Pennsylvania Legislature appropriating the sum of $600,000 for two years, and providing for the establishment and maintenance under the charge of the State Department of Public Health of one or more sanatoria for the free care of indigent persons suffering from tuberculosis.

Stony Wold Sanatorium.—The managers of this organization, which was incorporated for the purpose of taking care of consumptive working-women and children, succeeded in raising before March 1 the sum of $75,000 necessary to obtain a large donation made contingent in this stipulation, and the sanatorium is now entirely free from debt.

Contagious Diseases Hospital for Brooklyn.—By a decision of the Court of Appeals, rendered last week, New York City may proceed with the erection of a contagious diseases hospital in Hawthorne street, between Kingston and Albany avenues, Brooklyn. A person who objected to the plan to place such a hospital in this situation obtained a judgment at Special Term enjoining the city from the erection of the hospital. The Appellate Division reversed the judgment, and now the Court of Appeals upholds that decision.

St. John's Guild.—The fortieth annual report of this organization shows that the total number of children and mothers who last summer received the benefits of the Guild's floating hospital was 40,983.

Dr. J. R. Whiting has resigned as chief of the genitourinary clinic of Columbia University and as assistant attending genitourinary surgeon to the first surgical division of Bellevue Hospital. Dr. W. S. Reynolds succeeds him at the College of Physicians and Surgeons, and Dr. T. F. McCarthy at Bellevue.

Dr. C. G. Bandler has been promoted to the position of adjunct assistant attending genitourinary surgeon to the first surgical division of Bellevue Hospital and chief of the genitourinary clinic of the Out-Patient Department of Bellevue Hospital.

Dr. H. M. Archer of this city has been appointed honorary medical officer of city fire department, with the rank of chief of battalion.

The Pasteurization Bill at Albany.—The Reece pasteurization bill had a hearing before the Cities Committee in the Assembly of the New York Legislature on Tuesday of this week. Assemblyman Reece, speaking for his bill, said that infant mortality on Randall's Island dropped from 42 per cent. to 16 per cent. in a few years, following the introduction of pasteurization there. Health Commissioner Darlington opposed the bill because it involved mandatory legislation. He admitted that pasteurization was desirable under certain conditions.

Women Physicians in Europe.—Hungary is said to have only twenty-seven women physicians. The figures of the French Bureau of Education show that in 1906 there were 2,264 female students in the French universities, of which number 454 were studying medicine.

Postage Stamps costing 50 per cent. more than the regular issues are now on sale in Holland. The additional amount received is to be used by the government in the combat against tuberculosis.

The Jewish Maternity Hospital has opened its out-door department at 270 East Broadway, and applicants are received daily, except Sundays, between three and five P.M.

Obituary Notes.—Dr. Charles Reed of Brooklyn died on March 5. He was born in Ossining, N. Y., in 1856, and was graduated from the College of Physicians and Surgeons in 1879.

Dr. Thomas A. Skillman of New Brunswick, N. J., died on March 6 at the home of his daughter, Mrs. Ellis Warren, in Princeton, where he had gone to recuperate. He was injured in a trolley accident some time ago, which compelled him to give up active practice. He was graduated from the New York University Medical School with the class of 1878.

Dr. Clifton Scott of Des Moines, Ia., died on February 27, at the age of fifty-four years. He was born in Como, Ill., and in 1883 was graduated from the Louisville College of Physicians and Surgeons. After post-graduate work in Rush Medical College he began practice in Dickson, Ill., but has been a resident of Des Moines for the past seventeen years.

Dr. Alexander MacIntosh of Halifax, N. S., died on February 28, in his seventy-sixth year, after an illness of several weeks. He was born in South River, Antigonish County, and received his medical education from the University of Pennsylvania Medical College, from which he was graduated in 1858. He had practised in Antigonish for over thirty years although for the last fifteen years he had retired from active work.

Dr. J. M. Willis of Temple, Tex., died on February 24, at the age of eighty-five years. He was a native of Barnesville, Ga., and had practised in Waco since 1865. He retired from practice some years ago.

Dr. Lyman W. Bliss of Saginaw, Mich., died in San Antonio, Tex., on February 20, at the age of seventy-one years. He was born in Smithfield, N. Y., and served in the Civil War as surgeon of the Tenth New York Cavalry. He had practised in Saginaw since 1866, and in 1891 was elected president of the State Medical Society.

Dr. Robert Provan of South Brookline, Mass., died on February 24. He was born in New Brunswick, and received his medical degree from Harvard College in 1860. He had practised for many years in South Boston.

Dr. John Barker of Woodbridge, Conn., died on February 16, at the age of seventy-two years. He was graduated from the Yale Medical School in 1860, and, after practising for a time in New Haven, removed to Westville about twenty-five years ago. Five or six years ago he retired from active practice, although he continued to act as medical examiner in Woodbridge.

Dr. J. W. Parker of Kansas City, Mo., died on March 2, at the age of eighty-five years. He was born in Lexington, Ky., and, after receiving his medical education in that city, in 1853 began practice in Kansas City, at that time a village of 3,000 people. He continued in active practice until six years ago, when compelled to retire on account of failing eyesight.

Dr. George T. Church of Brooklyn died suddenly of heart disease on March 10, at the age of forty-nine years. He was a native of Waterville, N. Y., his father being the well-known Justice Charles Church. He was graduated from Hamilton College in the class of 1880, and, after some years spent in various teaching positions, studied medicine at the Albany Medical College and at Dartmouth. He practised for a time in Saratoga Springs, but some years ago removed to Brooklyn. He was one of the examiners of the Civil Service Board.

Dr. William B. Crain of Richfield Springs, N. Y., died of heart disease on March 9, at the age of seventy years. He was graduated from the University of Pennsylvania at the beginning of the Civil War and was assigned to take charge of the United States Military Hospital at Washington, D. C. Later he was assigned to the United States Hospital at New Creek, Va. He served with the rank of Major in the Maryland cavalry until the close of the war, and was at Antietam and other battles. From 1866 until his death he was a successful practitioner at Richfield Springs.

Dr. J. K. Cassel died at Philadelphia on March 2 at the age of seventy-two years. He was graduated from Pennsylvania Medical College in the class of 1861, and he served during the Civil War with the Fifty-seventh Regiment, Pennsylvania Volunteers.

Dr. Fred Suesserott died at Chambersburg, Pa., on March 2, at the age of fifty years. He was graduated from the Medical Department of the University of Pennsylvania in the class of 1871.

Dr. Wm. J. Butler died at Wilkesbarre, Pa., on March 4 as the result of injuries received in a railway accident. He was graduated from the Pennsylvania Medical College in the class of 1885.

Dr. J. Ward Steele died at Dover, Del., on March 4, at the age of thirty-three years.

RULE AS TO NEGLIGENCE IN *X*-RAY TREATMENT.

In February of this year a case was brought to trial before Judge Brady and a jury in the Supreme Court in this city, in which a well-known physician was charged with negligence, in that he "unskillfully, carelessly, and negligently administered to the plaintiff what is commonly called or known as *x*-ray treatment, whereby the hair on the left side of plaintiff's head was burned off, and her face and neck on the same side were greatly burned, hurt, and injured." The plaintiff, a waitress, alleged special damage in loss of wages and demanded judgment for $10,000. The case was left to the jury, who found a verdict for the defendant. In the absence of any reported case on this subject in any court in this State, the rules of law stated in the Judge's charge to the jury are of interest. Before considering them, however, the facts as they appeared in evidence should be considered.

The Facts.—The plaintiff, about thirty-five years of age, had had an operation for tuberculous glands on the right side of her neck. A large scar, with considerable loss of tissue, marked this operation. Subsequently, the glands on the left side of her neck were similarly affected, and she applied at a hospital for treatment, but refused an operation. She was then advised that *x*-ray treatment for this malady was often successful, and in the spring of 1903 she applied to a physician for that treatment. After several applications, he noticed on one occasion when she visited his office that she had developed a slight dermatitis. He then suspended treatment for about two weeks. Shortly after, and while still under treatment by this physician, she applied to the defendant for *x*-ray treatment, and during May, 1903, the two physicians treated her contemporaneously, each remaining in ignorance of the other's treatment.

In the fall of 1903 she had three treatments from the defendant at intervals of about ten days. A 16-plate Waite & Bartlett machine was used with a 5-inch General Electric tube. The surface of the tube was not less than 8 inches from the plaintiff's neck, and the exposure on each occasion lasted 8 minutes. Her head and shoulder were protected by sheets of lead foil, with an aggregate thickness of about 1/12-inch. Four or five days after the third treatment a dermatitis of the second degree began to develop, extending from the bottom of the neck to above the ear, and embracing the whole left cheek. She called on the defendant, who prescribed an antiseptic dressing and urged her to call again in a day or two. He saw her only once more, about ten days later, when the wound was purulent and dirty, and the hair about the ear had fallen.

At the time of the trial she had a network of telangiectases over the glands in her neck and extending into her cheek, and a slight sclerosis behind the ear. Her hair had grown again. The glands were still slightly enlarged on both sides of the neck. She had been examined in October, 1904, after suit began, and it appeared that the telangiectases had increased considerably since that time. She had had further *x*-ray treatment from a third physician in the interval.

The Expert Evidence.—The evidence of experts on both sides was that the duration of the treatment and the distance of the tube from the neck were regarded as safe, that the static machine was deemed safer than a coil, that the quantity and quality of the *x*-ray continually varied, not merely from day to day but in the course of a single application, that the protection by a lead sheath was the best known to science, and that no means was known to science of accurately measuring either the quantity or quality of the *x*-ray.

The Law.—On this state of facts, the Judge charged the jury upon the question of the physician's duty according to the familiar rule. (*Pike v. Honsinger,* 155 N. Y. 201). First, he must possess "only that reasonable degree of learning and skill relating to *x*-ray treatment commonly belonging to a physician and surgeon using that treatment in the city of New York in November, 1903." Second, he must use "only reasonable care and diligence in the exercise of his skill and the application of his learning in the treatment by *x*-ray." Third, he was bound to treat the plaintiff "according to his best judgment." The Judge pointed out that the defendant was here charged with negligence or breach of duty only in the actual treatment, the second branch of the duty imposed on him by law, as above defined. The possession of adequate skill and learning, and the exercise of best judgment were thus not in the case. Reasonable care and diligence in the treatment meant "such ordinary care and diligence as is usually given by a physician in good standing. It does not mean the highest possible care and diligence, or such care and diligence as might have been used by some other physician, or even by the defendant himself." The physician is not an insurer or guarantor, and "in *x*-ray he does not insure the patient against a burn."

The part of the charge of chief significance, however, was that in which the Judge dealt with the doctrine known as *res ipsa loquitur.* Briefly stated, that doctrine means that the accident and the surrounding circumstances speak for themselves, and afford *prima facie* proof of negligence. A common instance of the application of the doctrine is found in a railroad collision between two trains. The Court knows, and everybody knows, that when trains are operated with ordinary and reasonable care they do not collide, and the mere fact of a collision, therefore, affords evidence of negligence; the accident speaks for itself. But the Court here holds that the mere happening of an *x*-ray burn is not evidence of negligence, and it reached that conclusion doubtless in view of the evidence of the uncertain state of *x*-ray science and by analogy to cases of bursting flywheel of an electric machine, bursting oil tank, etc. (*Pichl v. Albany R. R.,* 30 App. Div. 166, affirmed 162 N. Y. 617; *Losee v. Buchanan,* 51 N. Y. 76; *Cosulich v. Standard Oil Co.,* 122 N. Y. 118; *Reiss v. N. Y. Steam Co.,* 128 N. Y. 103). In cases of this kind the accident does not speak for itself, because it may happen notwithstanding the use of reasonable and ordinary care. In the case of the bursting flywheel, Judge Landon, afterwards of the Court of Appeals, said that the doctrine *res ipsa loquitur* did not apply: "Because such are the limitations upon human foresight that every reasonable care does not always prevent accidents, and that such is the nature of steam and electricity, and the engines by or upon which they operate, that when such an explosion as this occurs our experience, or even expert experience, is not sufficiently uniform to justify us in presuming that negligence is the cause. The explosion does not in fact speak for itself and tell us its cause."

If this is true of steam and electricity *a fortiori* it is true of the much more uncertain science of *x*-ray. Upon this subject the Judge charged as follows: "If the jury find that the plaintiff received the burn of which she complains in consequence of the treat-

ment by the defendant, they cannot infer that the defendant was negligent merely because the plaintiff afterwards suffered from *x*-ray burn, for the cause of the burn may be beyond human knowledge, and even expert experience may not be sufficiently uniform to indicate a sure means of preventing it. Owing to the limitations of human knowledge, the exercise of every reasonable care does not always prevent accidents, and this is especially true in dealing with such comparatively little known forces as electricity and *x*-rays. The jury cannot find the defendant guilty of the negligence alleged in the complaint unless it can find in the proofs some particular act of negligence which caused the burn. To punish the defendant because he cannot explain the cause of the burn is not necessarily to punish him because he has done wrong, but may be to punish him because he does not know something which science cannot find out, or has thus far been unable to find out. That would be manifestly unfair, and the law will not do it."

This charge is the only judicial expression of the law of this State upon this subject so far as the reports show. It appears to be logically deduced from the analogies above referred to.

The attorneys were Black, Olcott, Gruber, and Bonynge for the plaintiff, and Charles Stewart Davison for the defendant. The counsel who tried the case were Irving L. Ernst, for the plaintiff, and Henry Winthrop Hardon, for the defendant.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

ERASMUS WILSON LECTURE—LEUCODERMA—CONDITION OF BLOOD-VESSELS IN SHOCK—SEQUEL TO ABDOMINAL SECTION FOR DILATED BOWEL—PERICARDITIS AND PLEURISY IN TYPHOID—AMALGAMATION OF SOCIETIES—THE EPIDEMIC—OBITUARY.

LONDON, February 22, 1907.

AN Erasmus Wilson lecture at the Royal College of Surgeons has at last been delivered on a dermatological subject. When the lectureship was founded by Sir E. Wilson it was intended that this should always be the case, though later Sir Erasmus yielded to the wish of the College Council to extend the scope of the foundation. Since then nearly thirty years have elapsed since a dermatological subject has been taken up by the Erasmus Wilson lecturer of the year. At length, however, dermatology has come to its own, and Dr. Willmott H. Evans on the 4th inst. took for his subject Leucoderma. In dealing with it and analogous changes in the pigmentation of the skin he took up a position in direct opposition to the leading authorities and textbooks. He maintains with confidence from very careful examination of the facts that in no way does the nervous system have any part in the production or localization of the patches of leucoderma. He thinks the action of some toxin derived from the alimentary canal may probably be the cause, this being aided by the action of light and sometimes by local injury. The mechanism by which the effect is produced he attributes to the vital action of peripatetic cells. That the familiar facts lend themselves to the first conclusion is obvious. The "tanning" which we see in summer and which so soon fades suggests that differences in color are physiological, and the same may be said as to the color of the different races of men. The tint of the skin in the white races is mainly due to the color of the superficial fat and blood-vessels, modified somewhat by the epidermal pigment which in darker races obscures the other factors. With regard to the common opinion as to a nervous origin it has been said that symmetry indicates this, but Dr. Evans maintains that symmetrical distribution is no sign whatever of connection with the nervous system, and, moreover, leucoderma is rarely symmetrical. He appealed to herpes roster as to which there is no disputing the nervous origin and that it affects only one side. He showed views of nerve areas, root and peripheral, and by means of numerous lantern slides proved that leucodermic patches do not occupy nerve areas. The association of leucoderma with some cases of nervous diseases sometimes spoken of he found so rare as to be mere coincidences. In drug pigmentation Dr. Evans ranged himself with those who consider it the effect of local action, the drug being found where the eruption exists—from which it also appeared that a poison circulating in the blood may be deposited in certain places and not generally. As stated, Dr. Evans considers a toxin from the alimentary canal the cause of leucoderma, as he does also of some analogous diseases. A morbid intestinal condition he found often preceded. The localizing factors he held were mechanical or chemical—trauma and light. The actual mechanism of depigmentation he compared with that of bleaching of the hair in old age which Metchnikoff showed was due to the action of macrophages which swallow the pigment and carry it away. He considered the superactivity of these macrophages was caused by the toxin—their activity waxing and waning according to the varying amount of toxin or of the local adjuvants. It was seldom that these peccant macrophages can be induced to retrace their steps and redeposit the pigment. Should they do so the whitened patches would resume their natural color, but the area affected usually remained free from pigment to the end of life.

The condition of the blood-vessels during shock was the subject of a paper by Mr. J. D. Malcolm at the last meeting of the Medico-Chi. He holds a view opposed to that of Dr. G. W. Crile which was founded on experiment and has been widely accepted, and which attributes shock to a paralysis of the vasomotor center and the consequent relaxation of the vessels throughout the body. Mr. Malcolm repeated the view he has previously proposed, that shock is due to a paralysis of the vessels in the splanchnic area. He said Dr. Crile's theory fails to account for the pallor and other facts, *e.g.* that the first effect of vasodilatation is to increase the volume of blood in the arteries; that fluids cannot enter the veins during extreme shock, or, if they did, would pass into the tissues; that the blood-pressure in the portal vein was raised; that the specific gravity of the blood of animals during shock was raised as shown by Corbett and Roy. These difficulties disappear if we accept Mr. Malcolm's contention that the arteries are contracted. He added that the most successful treatment is in harmony with his views. Stimulating vasodilatation and the application of warmth were the important indications.

Dr. Lockhart Mummery took up the cudgels on behalf of Dr. Crile's theory and asserted from his own experience that the arteries were not contracted, but were relaxed during shock. The capillaries, he said, were empty, but that was because the arterial pressure did not suffice to fill them and the pallor depended on this fact. Fluids entered the circulation easily enough in shock. The blood-pressure in the portal vein rose a little, but never higher than that of the arteries. Loss of heat beyond that caused by diminished metabolism was a doubtful matter.

Dr. Leonard Williams followed on the same side but said exhaustion of the medulla was only partial, so that relaxation was not complete during life.

Dr. A. Morison said the main thing in shock was cardiovascular paralysis, which occurred in different degrees. In the absence of pressure the elasticity of the arteries naturally diminished their caliber. Heat stimulated through the central nervous system.

Dr. Sheen concluded from his personal observation that the arteries were neither contracted nor dilated. In severe injuries the patient at first seemed to have little the matter which could be ascribed to rising pressure. Accumulation of blood in the abdominal veins soon followed.

Dr. Beddard said the first thing to explain was the fall in the general blood-pressure. The main factor was peripheral resistance and this depended on the condition of the microscopic arterioles. Pallor was due to accumulation of blood in the abdominal veins. Even the volume of a limb might be diminished in shock, but the chief point was diminution of resistance in the splanchnic area. The muscular tone was reduced and so the chief source of heat was lost. Hence the application of heat was of the highest importance, for the patient had become, so to say, a cold-blooded animal for the time. Nevertheless shock was not to be considered solely a vascular phenomenon.

The sequel to a case of extreme "dilatation of the rectum and colon as far as the hepatic flexure," for which abdominal section was performed in November, 1904, was related by Drs. Morley Fletcher and Betham Robinson at the last meeting of the Clinical Society. The dilated bowel contained many pounds of dark feces. This matter was squeezed out of the anus by pressure above. There was great hypertrophy of the bowel wall but no sign of peritonitis, no large glands, no abdominal band. The patient, a boy of twelve, did well and was exhibited at the

Society in April, 1905. The boy remained in good health until July when he was seized with abdominal pain and diarrhea and readmitted to the hospital in a comatose state and died next day. The post mortem showed that the dilatation had greatly lessened, the mucous membrane was healthy and no cause for the dilatation could be found. The points chiefly submitted by the authors were (1) absence of symptoms in early life; (2) suddenness of onset; great improvement after completely emptying the gut, followed by careful dieting, etc.; (4) duration of the improvement, and (5) the sudden termination with coma—possibly due to ingestion of some toxic substance or to some infection. In the absence of any condition that could cause obstruction the case might be called by the unsatisfactory term congenital or idiopathic. Some discussion followed as to the origin of such cases. The treatment was approved. It was remarked that the sphincter muscle sometimes showed changes, especially fibrosis, but Dr. Fletcher was able to say that in this case it was quite normal. He added that the circumference of the gut diminished by as much as five inches from the time of operation to that of the autopsy.

A somewhat obscure case was related by Dr. Hawkins of Reading, who had diagnosed it as typhoid fever with the very rare complications of pericarditis and hemorrhagic pleurisy. The patient was a girl of twenty and her first complaint was of sore throat and stiffness of her legs. Five days later she had a rigor followed by diarrhea. No spots appeared but during her illness the abdomen was distended and the bowels moved from twice to seven times a day. Widal's reaction was tested once with positive result. Early in the third week there was a systolic murmur at the apex and blood-stained expectoration which two days later was typically rusty, the physical signs indicating consolidation of left base. In the fifth week the condition seemed critical, respirations 42, pulse 128. Paracentesis was done and 142 ounces of hemorrhagic fluid withdrawn. Improvement followed, but temperature did not become normal until the seventh week. In the discussion doubts as to the case were expressed. One suggestion was that pneumococcal infection would account for the course of the disease and the temperature chart shown was not like typhoid. Another was rheumatic infection, as to which Dr. Hawkins said salicylates had been given for two days with a fall of temperature which rose again. The chief treatment had been hydrochloric acid which he thought the best antiseptic as a routine measure in typhoid.

Another step has been taken this week towards the amalgamation of our medical societies. At a meeting at the College of Physicians on Tuesday those interested in the scheme agreed upon the name of the united body, which is to be the Royal Society of Medicine.

Four fresh cases of cerebrospinal fever were admitted in Belfast yesterday and there were three deaths there, making a total for the week of 103 cases with fifty-seven deaths. The Health Committee decided to close the school which four children who had contracted the disease attended. A case in Hull admitted on Wednesday has proved fatal. Some other cases, sporadic they are assumed to be, have occurred in other districts. Eight cases were notified last week in Edinburgh, of which six died, but it was shown that two were not cerebrospinal fever. At Paisley the totals are eleven cases and six deaths. More cases have been reported in Dublin and other towns. The Irish Local Board has recommended local authorities to adopt notification. The M. O. H. of Cork says in that city this has remained in force ever since the outbreak of 1900.

Surgeon-General Sir John M. Donnelly, K.C.B., died on Monday at the age of seventy-six. He joined the Madras Army in 1856 and served in Burma from 1859 to 1874, filling various offices. In 1885 he became Deputy Surgeon-General and was in medical charge of the Burmese Expedition and for his service made C.B. He remained P.M.O. in Burma until 1890, when he was in the Chin Lushai Expedition, promoted to Surgeon-General and then retired. Last June he was advanced to K.C.B. He graduated M.D., R.U.I., 1855.

Deputy Inspector General Wm. Campbell Seaman, M.D., died last Friday at the ripe age of eighty-nine. The deceased officer, after distinguished service, had retired from the army many years and enjoyed a healthy old age. He was walking out last summer, but the severe winter proved fatal to him. He graduated M.D.Edin., in 1839, and the next year took the L.R.C.S. Ed.

The Abortion of Specific Diseases. In a well-reasoned article in the *Boston Medical and Surgical Journal* of January 31, 1907, Dr. J. M. French protests against the pessimism which denies the possibility of aborting a specific disease. If diphtheria can be aborted, he says, why not other infectious diseases, if the proper remedy be found?

MORTALITY IN PARIS—THE TREATMENT OF PHARYNGEAL CANCER—IMPALEMENT THROUGH THE RECTUM—SUTURE OF THE HEART—THE COUNTRY PRACTITIONER—ELECTRIC MEDICATION—NECROLOGY.

PARIS, January, 30, 1907.

An interesting study on the mortality in Paris during the nineteenth century was presented before the Académie de Médecine by Bertillon. The speaker pointed out the considerable reduction in the death rate in Paris that had taken place during the past hundred years, for, whereas at the beginning of the past century the figure was thirty-two to thirty-three per thousand inhabitants, at present it was only nineteen per thousand. This remarkable improvement was due especially to the reduction in infantile mortality. The causes of death that have contributed the most to the low death rate of to-day were the infectious fevers, principally typhoid fever and diphtheria. In addition to many diseases, the mortality of which had remained stationary, it was necessary to mention two which were more frequently fatal—cancer and nephritis.

In the Société de Chirurgie, Faure read a noteworthy paper on the treatment of malignant disease of the pharynx. He had found that the inverted position was useful in operating in these cases, and he did not resort to preliminary tracheotomy, as he considered that this increased the gravity of the prognosis. He had also given up preliminary intubation. The speaker then outlined the different surgical routes through which the disease might be attacked, which were, of course, different according to the situation of the new growth. For tumors limited to the tonsils he had found that a transverse incision below the angle of the jaw, with or without additional lateral branches, was the most useful. Through this incision it was easy to dissect the entire region, and, after excision of the ascending ramus of the jaw, to remove all the diseased portions of the pharynx, the tonsil, the base of the tongue, and the soft palate. However, the temporary or permanent resection of the ramus of the jaw was a serious mutilation that should not be resorted to when it could possibly be avoided. Operations of this sort, although admirable from the technical standpoint, were unfortunately very severe, and had a mortality of from 30 to 50 per cent. The results obtained also were only mediocre, and Faure had not been able to obtain a single permanent cure among his patients. In most instances the recurrence had taken place promptly, and only in one case did an interval as long as three years elapse. In summing up, he said that malignant disease of the pharynx was undoubtedly the most serious of the cancers amenable to operation. The surgical procedure was always a very severe one, but if carried out in time, while the lesion was still localized, it was possible to obtain, if not absolute cure, at least encouraging results, and under these conditions surgical measures in spite of their gravity should always be resorted to.

Baudet reported an interesting case of impalement of the rectum and perineum. The patient was a child of ten years, who, in climbing over a fence constructed of iron pickets with sharp points, lost his balance and was impaled on one of the spikes. The iron penetrated directly into the anus and emerged through the perineum a little behind the scrotum. In addition to a profuse hemorrhage, the little patient presented disquieting symptoms that suggested the possibility of a peritoneal injury. The peritoneum and the abdominal wall as high as the umbilicus were the seat of an enormous ecchymosis, and a small amount of blood escaped from the anus. Nevertheless, the urinary system was intact, for clear urine was withdrawn by catheter. Baudet, in order to avoid any risk of causing a possible peritoneal infection, did not make a digital examination of the rectum, but examined it by means of a bivalve speculum. In this way he discovered a longitudinal wound on the anterior wall of the rectum, beginning several centimeters above the anus and 5 or 6 cm. in length, but not reaching up to the peritoneal cul-de-sac. Baudet sutured this wound, as well as that of the perineum, and an uncomplicated recovery resulted in the course of a month. Baudet also reported another equally interesting case. This was a wound of the heart caused by a thrust with a foil, and successfully treated by suture. The patient was a man twenty-three years old, who, while fencing, received a thrust in the fifth left intercostal space and became unconscious shortly after the accident. The pulse was hardly perceptible, and an hour later Baudet reached the patient and exposed the pericardium by making a large, hinged flap. He then discovered the pericardial wound, from which a little blood was oozing. At this time the heart was almost motionless, and the wound, which involved the heart muscle itself, was easily sutured. By direct mas-

sage the heart was induced to beat again, and it was found that the hemorrhage was controlled by the sutures. The thoracic flap was replaced and sutured without drainage of the pleural cavity. The patient left the hospital at the end of twelve days, and when seen two months later was free from all symptoms.

The differences in the careers of country and city physicians were discussed by Reymond before the Société de l'Internat de Paris. He stated that the country physician usually had a most difficult and most important rôle to play, and ordinarily he exemplified the highest moral qualities, while his life was rendered arduous through the inadequacy of the remuneration he could receive from the peasants living in villages or on detached farms. The country physician theoretically should be a universal specialist, for he had only his own resources to count on, and frequently was unable to summon any colleagues to his aid. It was to be desired that in the interest of his patients the country physician should have had some experience in surgery and a grounding in several specialties, but unfortunately this was not always the case, and, for example, strangulated hernia, which ordinarily did not have a severe prognosis was frequently neglected until operation had been too long deferred because the practitioner did not have the skill to carry out the procedure necessary to relieve his patient. For this reason Reymond was interested in the question of establishing district hospitals, which would be useful not only from the standpoint of the patient, but which would also provide practitioners with a valuable source of instruction.

The action of electricity in causing remedial agents to penetrate the skin was discussed before the Société de Biologie by Tuffier and Mauté. They had experimented with trypan red, silver, and salicylic acid, and had found that these substances, by means of the continuous current, could be made to pass through the healthy skin. When brought into the tissues in this way they seemed to form different combinations with the cellular protoplasm than was the case when they were introduced by subcutaneous injection. The penetration of the substances used was always very superficial, however.

In the death of Prof. Pierre Budin, French obstetric art has lost one of its chief ornaments. His scientific labors were very diversified, and his busy life was devoted to two main ends. As a philanthropist, he had been struck by the ravages that ignorance of the laws of hygiene among the poor caused among their infants. He therefore started a crusade against this evil and founded the League for the Prevention of Infantile Mortality, which has for its object the education of mothers. As a teacher, Budin was able to systematize in admirable fashion clinical instruction in obstetrics, and it is largely through his offices that the students at present are enabled to receive the practical instruction they do in the maternity hospitals. He died, so to speak, on the field of battle, in the course of a journey through France, undertaken for the purpose of disseminating throughout the country an understanding of the importance of the combat against infantile mortality.

Emile Javal, one of the most illustrious French ophthalmologists, a member of the Académie de Médecine, has died. His name is well known in connection with the work he did on the subjects of astigmatism and strabismus. He himself became completely blind as the result of glaucoma, but in spite of his infirmity he was still able to work and lead a useful life. It was then that he wrote his book, "Entre Aveugles," which has been translated into most European languages.

OUR LETTER FROM COPENHAGEN.

(From Our Special Correspondent.)

RADIUM-EMANATION IN MINERAL WATERS—A NEW OPERATION FOR GLAUCOMA—THE CAUSE OF BOTHRIOCEPHALUS ANEMIA—INDICATION FOR MASTOIDECTOMY IN THE SPECIFIC GRAVITY OF THE PUS.

COPENHAGEN, February 22, 1907.

In the Medical Society of Christiania Prof. E. Poulsson read a paper on radium and its therapeutical effects. He drew the attention particularly to the fact that many of the usual mineral waters, *e.g.* the waters of Gastein, Baden-Baden, Karlsbad, Marienbad, Wiesbaden, Kreuznach, Bath, etc., contained rather large quantities of radium emanation and therefore possessed a relatively pronounced radioactivity. Perhaps this circumstance explained the fact that these waters appeared to act better when drank at the springs than when exported, because the water became destitute of the emanation when kept for a long time before being drank. The explanation might be expected to obtain, especially for those waters the composition of which approached very nearly to that of ordinary drinking water, *e.g.* Gastein, which latter spring has nevertheless enjoyed for centuries a reputation of healing powers. He also mentioned the experiments of Bergell and Bickell, that fresh water from the Kochbrunnen at Wiesbaden, added to human gastric juice, accelerated the digestion, or, in other words, that the radium emanation had an activating influence on ferments or enzymes, a quality well deserving of notice, as many mineral waters were famous for cure of affections of the digestive organs. In order to help those who could not afford to travel to the springs, it would be necessary, he said, to produce mineral waters artificially supplied with radium emanation. Experiments in this direction are now being made at the Pharmacological Institute of the University of Christiania.

In the same society Dr. S. Holth read a paper on a new operation which he had devised for the treatment of chronic glaucoma, and which he proposed to call "iridencleisis antiglaucomatosa." On these new principles he had operated upon forty-one glaucomatous eyes with very good results. When he reviewed the cases of chronic glaucoma operated on by him after the classic method of iridectomy, he was obliged to confess that the results were on the whole far from satisfactory. But in certain cases the results were good, and in all these it was seen that casually a little of the periphery of the iris had healed into the incision and formed a subconjunctival fistula, while the conjunctiva bulbi formed a flat bulla over one or both of the ends of the sclerocorneal cicatrix. Thereby he became convinced that though these operations, when judged after the rules of the classical method, were to be considered faulty, in reality they indicated the true way to a rational treatment, because instead of the failing physiological drainage they provided a new one of similar anatomical nature. In suitable cases of chronic glaucoma Holth therefore recommends that iridencleisis antiglaucomatosa be performed by drawing the iris out through the sclerocorneal incision and covering this by a conjunctival flap. When the operation succeeds, a subconjunctival bulla or localized edema forms itself under the conjunctival flap as a testimony of the recovered drainage, the fluid circulating through the eye now being led back through the subconjunctival lymph vessels. In one case an operated eye could later on be microscopically examined and showed that the iris was incarcerated in the sclerocorneal cicatrix and formed a fistula, the walls of which were covered by black pigmented epithelium. This finding supports the explanation given by Dr. Holth of the efficiency of the proposed operation. Prof. H. Schiötz and Dr. Kolstad congratulated Dr. Holth upon the good results of the operation as shown by the demonstrated patients.

In the Serum Institute of the State of Denmark T. W. Tallqvist, from Helsingfors, has carried out some interesting investigations into the pathogeny of pernicious anemia, especially the bothriocephalus anemia. In the proglottides of *Bothriocephalus latus* he has found, in addition to other substances, a fatty matter (lipoid), with strongly hemolytic qualities. He has shown by experiments on rabbits that this lipoid causes anemia, not only when injected under the skin or into the peritoneal cavity, but also when introduced into the intestinal tract. The experimental anemia produced in this way has a certain likeness to the pernicious anemia of man in respect to the hemoglobin value, the unaltered number of the leucocytes and the remittent course of the disease. This experimental influence discloses itself in an increased erythrolysis, as shown by the increased accumulation of iron pigment in the liver and in the spleen. It is highly probable that it is this lipoid substance that constitutes the blood-destroying poison in the bothriocephalus anemia of man, a resorption of the substance from the gut in certain cases causing the disease to develop. To obtain this result it is, however, necessary that a destruction of the proglottides sets in, as otherwise the active substance does not become free in the gut. Clinical experience shows that in reality in a considerable number of cases of anemia the parasite undergoes some alteration. Substances, in all respects similar to the lipoid of *Bothriocephalus latus* are found normally in the mucous membrane of the intestinal tract (and in some of the organs) of higher animals. These substances are also strongly hemolytic. As it is known that the so-called cryptogenetic form of pernicious anemia is nearly always accompanied by pathological processes in the digestive organs (the mucous membrane of the stomach), it is an obvious conclusion that the blood-intoxication is caused also in these cases by the lipoid substances originating in the diseased mucous membrane of the stomach. A lipoid substance similar to those mentioned above has finally been isolated by Tallqvist from carcinomatous tissues. This substance is also a pronounced hemolytic; perhaps, therefore, the anemia sometimes to be found in cases of cancer can be explained by a passage of lipoid substance from the new growth to the blood.

At a meeting of the Danish Otolaryngological Association Dr. P. Tetens Hald read a paper on the fixing of indications for the operative opening of the mastoid in cases of acute suppurative otitis media by means of the estimation of the specific gravity of the pus found in the external

auditory canal. Dr. af Forselles of Hekingborg had previously tried to establish that when the specific gravity of the pus exceeded 1,046 this was an infallible sign of empyema of the mastoid and indicated a mastoidectomy. Now, Dr. Hald showed that af Forselles had not paid due attention to the errors connected with the method employed for estimation of the specific gravity, so that at any rate the numerical value 1,046 was highly erroneous. But he showed further that, even if correct methods for the estimation of the specific gravity of the pus were used, it was exceedingly improbable that we might in this way get any help to establish with greater certainty the indication for mastoidectomy. Prof. Schmiegelow and Dr. Grönbech said that they had entertained considerable doubt as to the value of the method of af Forselles and congratulated Dr. Hald upon his having shown the fallacies of it.

AROMATIC SULPHURIC ACID IN TOXEMIA.

To the Editor of the Medical Record:

Sir:—Your editorial reference to the use of formic acid in the treatment of toxemia following diphtheria (February 2, 1907) has led me to give my experience with aromatic sulphuric acid. About twenty-five years ago I began using the acid in the treatment of boils, with very successful results. In fact, given in five-drop doses (in one teaspoonful of water) every two or three hours, it will cure boils. Later I had the same results with its use in carbuncle. In case of carbuncle, however, as in some other allied conditions, I have found it necessary sometimes to add quinine. My experience with boils and carbuncles led to the use of the acid in all forms of toxemia and blood-poisoning generally. I even use it in cases in which suppuration has already occurred. Aromatic sulphuric acid will arrest suppurative action. It will, if given in time, prevent suppurative action. I use the acid with opium in appendicitis. My results have been so uniformly good that I prescribe the remedy in all forms of toxemia. I have used it in the acute forms of nephritis complicated by pregnancy. In all cases of blood-poisoning my experience with over two hundred cases shows the acid to be a specific in case of chronic ulcer and sloughing ulcer. I give the aromatic acid internally and use carbolic acid externally. The simple dilute acid will not give the same results as the aromatic acid. In this connection I would add to my previous notes on carbolic acid that I have this winter injected two tuberculous tumors of the neck with pure carbolic acid (liquefied crystals), in each case effecting a cure and leaving only very small scars. I have also injected a cancer of the breast with the acid—carbolic—and have so far brought about a considerable reduction of the size of the tumor.

Accessory Nasal Sinuses, from the Rhinological Standpoint.—C. A. Richardson gives a summary of the symptoms of and methods of diagnosis in inflammation of the nasal accessory sinuses. He calls attention to the variable factor of pain, both as to its presence and location. The *x*-ray promises much in the elucidation of doubtful cases, except that it affords no clue to the condition of the sphenoid sinus, but it is of value in determining the condition of the ethmoid cells.

The Accessory Sinuses from the Ophthalmological Standpoint.—W. C. Posey considers it beyond dispute that sphenoiditis and ethmoiditis may excite retrobulbar inflammation of the optic nerve of varying degrees of intensity as well as paresis and palsies of the ocular muscles. Orbital abscess with resulting displacement of the globus occurs frequently. Apparently simple muscles of the lacrymal sac have proven at operation to have arisen in the lacrymo-ethmoidal cells. Sinus disease may also cause edema of the eyelids. This symptom is regarded as of great importance by the author. The conjunctiva has been turgid and studded with follicles in other cases, where the nasal disease seemed to have involved the nasopharynx rather than the sinuses; dendriform ulcer of the cornea appeared to be dependent upon an ethmoiditis in one instance, and change in the refraction of the eye, occasioned either directly by the pressure exerted upon the globe by the wall of a dilated sinus, or perhaps indirectly as a consequence of congestion and spasm of the ciliary muscle, has been observed not very infrequently. The author states that he has not been able to satisfy himself that ocular conditions other than these were actually dependent upon a sinusitis.

Shreds in the Urine in Their Relation to Prognosis and Diagnosis.—De S. Saxe makes a careful study of this subject. He finds that the shreds are best studied after proper fixation in stained specimens according to the methods outlined, Unna's polychrome stain being the preferred reagent for routine work and Gram's stain when gonococci are to be demonstrated. Urethral shreds proper may be divided into four varieties: Pus shreds, mucopus shreds, mucus shreds, and epithelial shreds, each of which have special naked eye and microscopic characteristics. Several varieties of altered epithelia are found in urethral shreds. Those undergoing hyaline changes may be identified not only by the iodophile reaction, but by a peculiar degeneration as shown by their staining qualities with polychrome methylene blue. Shreds composed of pure epithelia consisting of flat pavement cells with small nuclei are shed spontaneously, or after instrumentation, in the stage of the disease in which the superficial layers of the urethra become lined with squamous cells under the influence of subjacent, submucous lesions. Shreds from the prostate and vesicle include several special varieties which can be recognized under the microscope, but cannot be identified with the naked eye. The so-called comma shreds in reality may be one of two varieties of structures. The true comma shred of Fürbringer consists of hooklets of stratified epithelia, derived from the prostatic duct. A false variety of comma shreds is composed of bits of mucopus shreds which roll up into a lump at one end. The frequency of gonococci in urethral shreds is directly as the proportion of pus cells, and inversely as the proportion of mucus and epithelia in the specimens. This rule does not apply to prostatovesicular shreds. The study of shreds is not of great value in the localization of the affection in the anterior or the posterior urethra. The presence of prostatic or vesicular shreds which can be recognized microscopically is an aid to the localization of the process. The study of urethral shreds is most valuable in determining the stage of the process, the order of appearance being, with certain reservations, as follows: Pus shreds; mucopus shreds; mucus shreds; and epithelial shreds. In the prognosis the variety of urethral shreds present can have but a limited use. The fewer the shreds and the fewer the pus cells therein the better the prognosis. The larger the number of gonococci and of pus cells the worse the prognosis is as a rule. Marriage should not be sanctioned unless the terminal shred or shreds contain no pus cells for months, even after provocative measures, such as the drinking of beer.

Trypsin in Cancer.—W. S. Bainbridge says that the report by Morton, in the Medical Record of December 6, 1906, of benefit following the use of trypsin for cancer was premature. He says the specimen examined, upon which was based the pathological report seeming to demonstrate curative action of trypsin, was taken from near the nipple and not from the periphery of the growth. After this operation Bainbridge gave trypsin in much larger dose and alternated it with amylopsin. Twenty-four days after the operation referred to a third operation was undertaken to remove some enlarged nodules and secondary deposits in the skin which had appeared after the second operation. The pathological reports on these secondary growths showed the presence of malignant cells, which, from the abundance of mitotic figures, would seem to have been in an active state.

Journal of the American Medical Association, March 9, 1907.

Laminectomy.—H. M. Sherman reports a case in which he attempted to make an osteoplastic laminectomy of the cervical vertebræ in the removal of a growth producing pressure symptoms in that region. The difficulties of the operation are detailed, and he concludes from the results that a simple laminectomy in this case would have been the better operation, saving time and tissue. The operation which would be the better one in the kyphotic dorsal region is not so satisfactory in the lordotic cervical spine, where the preservation of the laminæ is not essential for the saving of the function of the extensor muscles. The impossibility of an accurate anatomic suture of the muscles that are divided in making the flap and the possibility of seriously interfering with their innervation are matters also to be considered. The surgeons with whom he corresponded were all in favor of the simple laminectomy in this region. He still thinks, however, that an osteoplastic operation may have its place in case of vertebral tuberculosis in which the angular deformity is practically a right angle; here the sawing of the bone would prevent undue compression of the cord, otherwise unprotected, by the muscles.

Multiple Neuritis Simulating Progressive Muscular Atrophy.—Three cases, one of alcoholic polyneuritis,

one of lead paralysis, and one of progressive muscular atrophy, illustrating the futility of attempting to differentiate these conditions by objective symptoms alone, without study of the etiology and course of the disease are reported by J. Grinker, who holds, nevertheless, to the advisability of clinically separating the cornual from the peripheral lower neuron disorders. His conclusions are given as follows: 1. Clinically, multiple neuritis may simulate a spinal atrophy as regards distribution of paralysis, absence of sensory symptoms, and protracted course. 2. Progressive spinal muscular atrophy may resemble neuritis in the presence of pain, remission of symptoms, and subacute course. 3. Etiology and course are still the best guides in the clinical diagnosis of the various muscle atrophies.

Tumors in the Inguinal Canal.—W. L. Peple reports three cases of this condition in young married women, all of whom had had children. In two, the growth sprang from periosteum or fascia covering the inner face of the ilium, while one lay encapsulated in the inguinal canal, attached only to its coverings. All were of comparatively rapid growth, the average from the first time of observation to operation being twenty-two months. In one case, pregnancy seemed to accelerate the growth. All the growths were apparently fibromata that had undergone myxomatous degeneration, and, while two were distinctly benign in appearance, the other was somewhat suggestive of sarcoma, though not identified as such. He considers the cases somewhat unique, both as regards the growths and the microscopic findings.

The Ripening Operation for Immature Senile Cataract.—The difference of opinion in regard to the important question as to use of the ripening operation for immature senile cataract is remarked by F. C. Todd, and to secure the most recent opinion on the subject he addressed letters to a number of leading ophthalmologists and received sixty-nine replies, which he analyzes and discusses. He believes himself that the ripening operation is imperative in some cases for humane reasons, and reports a case which he thinks illustrates this. The operation is contraindicated in cases complicated with high myopia, choroiditis, or other inflammatory conditions in cases predisposed to glaucoma or where adhesion to the iris is present. It is also not needed when a cataract is nearly mature or in patients over sixty, when the cortex is of such consistency that it can be removed without much difficulty. Nor would it seem needed in the case of well-behaved patients, when irrigation can be used by an operator skilled in his practice. Admitting the advantages of irrigation, he concludes that the ripening operation is indicated: 1. In case of immature cataract (not contraindicated as mentioned above), in which a preliminary iridectomy is to be performed. 2. In those patients who would not be likely to behave well during the extraction, thus preventing the operator from performing much toilet or from practising irrigation. If irrigation be not practised, trituration of the lens would be indicated in all patients with immature senile cataract under sixty, in whom, for special reasons, relief is required.

Turnip-Top Treatment of Chronic Diarrhea and Dysentery.—C. Wilson and H. E. Pressly report six cases, four of chronic diarrhea and two of amebic dysentery, microscopically diagnosed, which were successfully treated with a diet of "greens" composed of turnip tops. One of these patients, on going where the diet was not to be had, suffered a relapse and died, the others continued well. Other vegetables, such as mustard, phytolacca, and spinach are also mentioned as having been used to some extent. The attention of the authors was first called to the remedy by the recovery of an apparently hopeless case on "poke salad" (phytolacca) after leaving their care. Of the two cases of amebic dysentery, one patient had tried all the ordinary remedies and was ready to undergo an appendicostomy or an enterostomy if it would relieve him, as his condition was extreme. The other was not so bad, but had given up his work and never expected to be able to take it up. Both made good recoveries under the "turnip greens" diet. Wilson and Pressly have also tried it in two cases of well-defined gastric ulcer, in one successfully. The other patient was nearly moribund, and while he was able to take the diet better than anything else, it failed to save him. The method of cooking is important, as it is very unpalatable if not properly prepared. As prepared as a domestic dish in the South, ordinary bacon is used, boiled half an hour, and then the turnip tops, spinach, mustard, or phytolacca tops are added and allowed to boil from one to two hours.

The Lancet, February 23, 1907.

Cellulitis of the Spermatic Cord.—F. C. Madden reports a series of cases presenting symptoms of strangulated hernia, but which on operation have shown an empty hernial sac in the center of the swollen inflamed tissues described below. The clinical features of the cases are summarized as follows: The patients generally complain of severe pain in the scrotum and around the lower part of the abdomen on the affected side, with constipation and some vomiting, which, however, is not usually a prominent symptom and is generally remarked only at the first onset. The temperature is raised and the general condition may be decidedly bad. On examination the side of the scrotum appears to be filled with a large rounded swelling which runs right into the region of the external ring—in fact, presents all the appearances of an irreducible inguinal hernia. On palpation, it will be noted that the skin is edematous and the swelling is hard, but doughy on firm pressure, runs well down into the scrotum, and cannot be reduced. There is no impulse on coughing and the whole mass is dull on percussion. The general impression in such cases is that it is impossible to be sure whether we have to deal with strangulated hernia or not, but in any case immediate operation is the proper treatment. An incision is then made over the lower part of the abdomen and the neck of the scrotum, through a markedly edematous skin, and several layers of thickened infiltrated edematous structures are divided, but still no gut is found nor even clear fluid within a sac. Finally, after separating off all the different layers, which are firmly glued together by lymph, a thick inflamed rope-like structure is met with which runs distinctly up into the abdomen through the internal ring. On removing this cord between ligatures, the upper one as high up as possible, it is seen that it consists of a much infiltrated spermatic cord, the veins in which are all thrombosed and filled with purulent clot, while the rest of the structure is thickly studded with small abscesses, or rather collections of pus scattered throughout a kind of spongy tissue in its whole length. On the removal of this portion of the cord an elongated hernial sac of thickened inflamed peritoneum, its serous surfaces adherent with lymph, may sometimes be found and ligatured off at the level of the internal ring. On the completion of the operation a gutter is left, formed by the opening up of the inflamed coverings of the cord and scrotum, and this is packed with gauze and the whole wound is allowed to granulate up from the bottom. The testicles are not affected as a rule, but, as their functions must be quite abolished by the block in the cord, they are usually removed, a procedure which materially simplifies the subsequent course of treatment of the case. After running a modified septic course the patients usually do very well. One case has resulted fatally from extension of suppuration along the retroperitoneal tissues leading to diffuse septic cellulitis. Madden suggests that the condition may be a primary phlebitis with septic thrombosis of the veins of the spermatic cord, though he is at a loss to explain such a lesion without some original septic infection which the cases in question have not presented.

Infective Endocarditis Cured by the Inoculation of a Vaccine Prepared from Organisms Found in the Patient's Blood.—A case is detailed by J. Barr, W. B. Bell, and S. R. Douglas, the inoculations being regulated by the examination of the opsonic power of the patient's serum. The patient was a woman of twenty-five years, who began with a sore throat followed by a large, soft swelling behind the angle of the left jaw. This disappeared in three days. About a week later a continuous high temperature was noted. Antistreptococcus serum was injected without appreciable result. In about a fortnight from the beginning of the case evidences of endocarditis of the right ventricle were present. A small abscess appeared in the foot and a streptococcus was isolated. Later a pure culture of streptococcus was isolated from the blood and a vaccine was made therefrom, according to the method of Wright. The treatment was thereafter carried on along the lines indicated in the title of the paper, and the patient made a complete recovery. The authors say that the problem in these septicemic cases is whether the presence of an area containing living and multiplying bacteria, which from time to time have free access to the blood stream, is at all favorable for the manufacture of antibacterial substances by the infected organism or whether a more efficient production would take place if the bacterial products were brought into actual contact with the cellular tissues and had to pass through the lymph stream before reaching the general circulation.

Condition of the Blood-Vessels During Shock.—J. D. Malcolm takes exception to the idea expressed by Crile that in a state of shock the blood-vessels are paralyzed throughout the body and that this is due to an exhaustion or breaking down of the vasomotor centers. He claims that the superficial capillaries are not dilated during shock,

and no evidence has been advanced to show why it is that their distention does not occur as a consequence of the paralysis of the muscular coats of the blood-vessels which is said to exist. Crile claimed that the fall of blood pressure which he invariably found during shock must result as an exhaustion of either the cardiac muscle, cardiac centers, blood-vessels, and vasomotor centers. He excluded the first three and fell back on the fourth. This argument is based on the assertion that a lowering of pressure in the carotids must depend on a relaxation of some part of the vascular system. This statement Malcolm considers as an untenable proposition. It appears, says he, to be founded on the idea that a contraction of the arteries causes a rise of blood pressure and a relaxation causes a fall. But this is a very incomplete and inexact statement of the well-recognized law that the small arteries exercise a regulating or stopcock action on the flow of blood to the tissues. When fully set forth an essential part of the stopcock mechanism is that a contraction raises the pressure in the large vessels, but at the same time lowers the pressure in the smaller ones, in those beyond the point where the stopcock is supposed to act. Hence, if any vessel has its lumen sufficiently contracted the blood pressure in it will be lowered. Malcolm believes that in this fact we have the true explanation of the fall of blood pressure in shock. The author is convinced from clinical observation that the larger internal vessels, arteries as well as veins, spout more forcibly if divided when the patient approaches a condition of shock than they do if the operation is not severe. He has noted this particularly in the cystic branch of the hepatic artery, renal arteries, and larger mesenteric arteries, and believes it due to the fact that these large central vessels, both arteries and veins, are unusually full. A rise of blood pressure in the large vascular trunks of the internal areas is fully accounted for if the vessels throughout the body contract and if the superficial vessels are more tensely contracted than the central ones. A difference between the superficial and the central areas in this respect ought to exist, for a low temperature acts powerfully in contracting the vessels and the superficial temperature falls markedly in the state of shock. Moreover, the smaller vessels have comparatively a much greater muscular power than the larger. Thus all the conditions tend to collect the blood towards the center of the body if his view is correct. But there is no evidence of paralysis of the vessels anywhere. Concerning the effect of adrenalin in shock, he says that the administration of this remedy here is not free from risk. During recovery from shock if, as he believes, the vessels are relaxing, saline injections should be useful. And at this stage fluid enters the vessels from the rectum almost as quickly as by direct injection. Theoretically, and he thinks practically, injections into the cellular tissue are to be preferred to those into a vein, if some such treatment is considered desirable during shock, because if the fluid does not find its way into the vessels from the cellular tissue an attempt to force it into a vein is likely to be not only futile, but also harmful. He regards the usefulness of injections with a view to increasing the bulk of the blood as very limited in cases of uncomplicated shock.

British Medical Journal, February 23, 1907.

Antistaphylococcic Serum in Furunculosis.—R. T. Thorne refers to the case of a woman of forty-five years with furunculosis of the face and body, lasting over a period of three years. Various remedies failed to give any permanent relief. He therefore made six injections of a vaccine prepared from the pus of a mature furuncle, commencing with 0.5 c.c. and increasing up to 2 c.c., leaving ten days between each injection. These caused no discomfort whatever, and from the date of the first injection to the present time (six months) no fresh furuncles have appeared and the patient is in perfect health.

Acute Intussusception.—A case is reported by W. G. Williams whose patient was a boy of three years, who fell down some steps and complained at once of some severe umbilical pain, which disappeared, but soon returned. Seen half an hour later he presented a condition of partial collapse with frequent pains, but no vomiting. There was a distinct swelling in the right iliac fossa, and extending rather higher up than the usual ileocecal variety, and this was more pronounced during the attacks of pain. Vomiting commenced in about an hour after the accident happened. The patient was at once placed under the influence of morphine, and three hours after the accident an injection of sterilized warm water was given by means of a catheter connected with an india-rubber tube and funnel. After injecting about a pint into the bowel the author placed his right hand over the swelling, while with his left hand he grasped the abdominal wall and small intestine and pulled gently downwards and towards the left side; suddenly, to his satisfaction, the swelling disappeared from under his right hand. He regards it as of the utmost importance in acute intussusception that the patient should be seen and diagnosed early, and at once put under the influence of morphine. An attempt at reduction should also be made as soon as possible, as in this way a good many lives can be saved. In this particular case an injection only was not sufficient, but a little traction applied worked admirably.

Rupture of Dilated Aorta Leakage Bruit.—F. B. Skerrett was called to see a man of seventy-one years who had collapsed while at stool. He found him pale, unconscious, with pupils widely dilated, and lips blue. The pulse was not perceptible at the wrists, and he was only taking short breaths at intervals. On auscultation over the precordial region the cardiac sounds could be heard feebly, but distinct from a continuous adventitious sound which may be described as "gurgling" or "lapping," as of a cat lapping milk. The bruit, which altered in character, the successive laps becoming more rapid and finally lost, was quite different from any sounds I have ever heard in the chest, and suggested at once the leakage of blood. It was thought the man had ruptured his heart muscle. He rapidly succumbed. At the post-mortem examination the pericardium was greatly distended with dark fluid and clotted blood. The heart was hypertrophied, but no rent in it could be found. In the external wall of the aorta were seen large dark-bluish areas almost encircling the vessel. They looked like gangrenous patches, but were really blood-clot infiltrations. The first part of the aorta was somewhat dilated and very atheromatous in parts, and in the inner coats of the wall near to the pulmonary artery was an irregular longitudinal valvular slit quite one and one-half inches in length, through which the blood had leaked. From this it had traveled in the coats of the vessel, and escaped into the pericardium posteriorly. The valves of the heart were in good condition. The rectum was found loaded. The man had not had any symptoms, his only trouble being a chronic bronchitis. A point to remark about the bruit heart was its total independence of the cardiac sounds. Presumably in rupture of the ventricle the sound of leakage, if ever heard, would be intimately related to the cardiac systole.

Merycism or Rumination in Man.—An elaborate study of this symptom is made by E. M. Brockbank, who gives the histories of a considerable number of personal cases. He refers to the medical history of the trouble, and then takes up the questions of mode of onset, power of combat, general health, etiology, age, sex, chemistry, varieties, pathology, mechanism, diagnosis, and treatment. He notes that in children imitation plays an important rôle. In his own experience the affection has come on in very early life, more often below the tenth year. The sexes have been equally involved. It may develop after an infectious fever or follow a blow on the stomach. Disorders of the latter organ frequently precede it, and constipation is a frequent coincident symptom. Many of the cases are very neurotic. As far as known, no chemical defect in the stomach has any causative relation to the attacks. As to treatment, the author says that in many cases, especially in the poorer classes, it is probably useless trying to control the ruminating act when the phenomenon may be called physiological. In the more intelligent classes, by practice, an expiratory effort, at the time of the development of the negative pressure in the thorax, might have some good effect, and cases have been published in which by an act of will the process could be brought on or warded off. The subjects of rumination should be advised to eat their meals slowly, taking considerable pains to chew the solid food well before it is swallowed, and to avoid all specially predisposing foods. They should also take very little fluid with their meals. No simple stomachic drugs have been of any use in controlling the rumination. Smoking acts as a deterrent in some instances. Where there are any concomitant dyspeptic symptoms these should be relieved, and should they have been the exciting cause of the rumination, their relief would probably benefit the merycismus. If the subjects of rumination feel ill after suppression of what is to them a natural process, they must on no account interfere with Nature's demands.

Berliner klinische Wochenschrift, February 25, 1907.

Magnet Operations on the Eye.—Hirschberg says that during the twenty-seven years that have elapsed since he first removed a fragment of iron from the depths of the eye by means of the electromagnet he has repeated the operation 347 times. He considers that it is ill-advised to refrain from attempts to remove a foreign body from the eye on the ground that it may become harmless through

encapsulation, and expresses his conviction that sooner or later the visual power of such an eye will be seriously impaired or totally destroyed. For diagnostic purposes both the *x*-ray and his own instrument, the sideroscope, should be made use of. It is a mistake to believe that the magnet itself can be used to establish the presence or absence of an iron particle in the eye, for the belief that if on approaching the instrument no pain is caused no foreign body can be present has been proved to be erroneous by many cases in his own experience. The author describes two of his most recent cases in which the successful removal of the foreign body by means of the magnet was of especial importance since the eye in question was the only one with which the patient was able to see. In the one case the injury was recent, and a splinter measuring 3.75 by 1.75 by 2 mm. was removed. In the other case the foreign body had entered the eye over a year and a half previously, but was also removed without complications, although the patient's visual power had already begun to show serious impairment.

Observations on the Importance of Mother's Milk During the First Period of Infancy.—Salge says that the importance to the infant of receiving mother's milk during the first period of its existence cannot be sufficiently emphasized, and that no physician should permit artificial food to be used if it can possibly be avoided. In analyzing fresh milk the mistake is frequently made of taking a sample for examination before the child has begun to nurse. Such a sample will always have a low fat content, because the amount of fat in the milk increases steadily during each of the infant's meals. To obtain a proper sample it is necessary to take some of the milk at the beginning and also at the end of each nursing for twenty-four hours, and then make the determination on the mixture of all these. If artificial nourishment is absolutely necessary overfeeding must be carefully avoided, and the author's rule is never to have the intervals between meals less than three hours. At the most, six to seven meals a day should be given, and during the first week the total amount of nourishment should not exceed 250-300 c.c. daily, gradually increasing to 600 c.c. in the course of the first four weeks.

Deutsche medizinische Wochenschrift, January 31 and February 14, 1907.

Calomel as an Antiseptic.—Theopold speaks highly of the value of calomel as an antiseptic for general surgical use and especially in obstetric practice. It has been employed under his direction in from 4,000 to 5,000 confinements conducted mainly under the care of midwives and the results have been extremely satisfactory. The agent owes its safety to its insolubility in water and watery fluids, while its antiseptic property appears to depend on its capacity to produce coagulation of albuminous substances when brought into close contact with them. Experiments with pathogenic bacteria have shown that its antiseptic value is quite high, and that when applied to a given surface it is perfectly capable of preventing infection by small amounts of bacteria. If it is applied together with iodoform a mutual decomposition results with the formation of the iodide of mercury, and the antiseptic action produced is much greater than that of either agent by itself. As ordinarily used there appears to be no danger of causing intoxication by the application of calomel for these purposes, and the author warmly commends it as a dusting powder to be applied to the hands after these have been sterilized in the usual way before performing any obstetric manipulations.

Observations on Hay Fever.—Wolff-Eisner dwells upon the necessity for making an accurate diagnosis in cases suspected to be true hay fever in order to distinguish them from nervous coryza, nervous asthma, etc. In order to do this it may sometimes be advisable to resort to the use of a diagnostic pollen extract. This can be prepared by triturating in a mortar pollens of the different varieties encountered in the locality in question, adding salt solution or plain water, centrifuging, and using the clear fluid. He speaks highly of the use of nose filters and protective eyeglasses with padded rims as prophylactic measures, but does not consider that Dunbar's serum is a true antitoxin. In order to prove a point denied by many, namely, that the conjunctiva alone may in some cases be susceptible to the irritating properties of the pollen, he describes his own case. Ever since being exposed to the pollen of rye, while collecting this in the fields for experimental purposes, he has suffered from a very marked idiosyncrasy to the influence of pollen, but this has always manifested itself only through conjunctival symptoms and there has never been any involvement of the nasal mucosa.

Hemorrhagic Complications of Scarlatina.—Klose, in discussing these complications as well as hemorrhagic conditions in children in general, states that he has found the treatment by the injection of gelatin solutions the most satisfactory. He usually employs a 10 per cent. solution and administers 20 c.c. at a time. For the site of injection he recommends the axillary region midway between the anterior and posterior axillary lines, which he says is also very well suited for the injection of diphtheria antitoxin. The skin in this situation is freely movable, and overlies a satisfactory cushion of fat and connective tissue, while lymphatic glands for absorption are close at hand. If the gelatin solution is carefully prepared the much dreaded danger of tetanus need not be apprehended.

Münchener medizinische Wochenschrift, February 12, 1907.

The Etiology of Erythema Nodosum.—Hildebrandt reviews the reports of a number of authors which appear to indicate that erythema nodosum is not infrequently associated with tuberculosis and describes a case of his own which he considers lends color to the view that there may be an intimate relationship between the two conditions. His patient was a young woman of twenty-four years, who had had enlarged cervical glands in childhood and came under observation with an acute angina and stomatitis. Ten or twelve days later she developed erythema nodosum, and during the acute period of the affection, while new eruptions were still appearing, the urine gave a positive diazo reaction. On injecting some of the patient's blood into two guinea pigs both animals developed tuberculosis, while no other organisms could be discovered in the blood. Somewhat later, first a right-sided and then a left-sided pleurisy followed by pericarditis developed and an infiltration at the right apex could be detected, so that these were all regarded as manifestations of a tuberculous process. Therefore at the time when the erythema nodosum appeared virulent tubercle bacilli were circulating in the blood. The author is of the opinion that while erythema nodosum occurring in a tuberculous patient does not necessarily depend on the tuberculous infection, it may be possible, though it has not yet been proven, that tubercle bacilli may give rise to a disease process that cannot be distinguished from the ordinary erythema nodosum.

French and Italian Journals.

Genesis of Pulmonary Anthracosis.—Francesco Feliciani gives the results of experiments on animals to ascertain the origin of pulmonary anthracosis. The animals were fed with materials containing coloring matters with a view to find out whether these substances would appear in the lungs or other organs. His conclusions are given thus: Experimental ingestion of carbon or carmine in powder does not produce a corresponding pigmentation of the lungs. Those powders ingested do not traverse the intestinal mucosa and do not appear in the liver or mesenteric glands. Injection of powder into the peritoneal cavity does not produce anthracosis in the lungs. Since the biology of germs varies from that of inert powders we cannot say that the same is the case with bacteria, such as the Koch bacillus.—*Il Policlinico*, December, 1906.

Regeneration of Nerve Fibers.—Aldo Perroncito concludes his researches on the regeneration of nerve fibers thus: At the central nerve stump there is a rapid new formation of nerve fibers in continuous lines. The axis cylinder degenerates, but is regenerated by lateral germs or division of the old axis cylinder near its cut extremity. The fibers penetrate the cicatrix and reach the peripheral fragment, anastomosing in its substance. Suture of the nerve assists regeneration by bringing the fragments together, and directing the course of the new nerve fibers to the peripheral stump. Some fibers of the peripheral fragment degenerate; others become club shaped at the ends. The new fibers surround the degenerated ones. The process of repair is not always the same in similar lesions. The return of function is not always proportional to the amount of repair. Electrical conduction in a nerve begins first in the peripheral fragment. No functional activity can be demonstrated in nerves that do not show repair changes. Suture facilitates repair and reestablishment of function.—*Archivio per le Scienze Mediche*, Vol. XXX, Part 5.

Syphilitic Arthropathies.—Guido Marino reports two undoubted cases of syphilitic joint affection because there has been much doubt thrown on the existence of true syphilitic joint lesions. There are two types of syphilitic joint affections. Gummatous infiltration begins in the perisynovial tissues. In another type the lesion is primarily of the bones. The synovial membrane remains intact or is involved secondarily. The effusion that takes place is only a reaction at a distance from the periarticular inflammation. There is articular motion that is relatively pronounced and little pain in movement. These facts show the normal condition of the synovial membranes.—*Il Policlinico*, January, 1907.

Book Reviews.

THE PRACTITIONER'S MEDICAL DICTIONARY. An Illustrated Dictionary of Medicine and Allied Subjects, including all the Words and Phrases Generally Used in Medicine, with Their Proper Pronunciation, Derivation, and Definition. By GEORGE M. GOULD, A.M., M.D., Author of "An Illustrated Dictionary of Medicine, Biology, and Allied Sciences," "The Student's Medical Dictionary," "30,000 Medical Words Pronounced and Defined," "Biographic Clinics," "The Meaning and Method of Life," "Borderland Studies," etc.; Editor of *American Medicine*. Philadelphia: P. Blakiston's Son & Co., 1907.

THIS is a new dictionary (not a revision) similar in style and in get-up to Dr. Gould's other dictionaries with which the profession of this country is already so familiar. In the matter of completeness, as regards the number of titles, it seems to be between the large "Illustrated Dictionary" and the "Student's Dictionary" of the same author. It is of very convenient size and weight, with flexible cover, and bound so as to lie flat on the table wherever opened.

Among the new features in which this dictionary differs from the others by the same author is the distribution of the eponymic terms throughout the book in their alphabetical order instead of their grouping in a table under the one head, "disease." The same principle might profitably, we think, have been extended by breaking up the other tables of signs, symptoms, tests, etc., and distributing their single titles alphabetically. The Basle system of anatomical nomenclature [BNA] has been introduced. In the definitions of drugs the dosage has been given in the metric as well as the apothecaries' system, and the definitions have been changed, where needed, to conform to the directions of the new Pharmacopœia; in the spelling of the alkaloids and chemical terms, however, the dictionary departs from this authority, which we cannot but regard as unfortunate, since the Pharmacopœia is the standard, and if its authority is accepted in the matter of names and preparations it should be also in that of spelling of official drugs. However, the dictionary will not be consulted much for its spelling but for its definitions, and in this respect and in the number of new terms defined the work is one of surpassing excellence. We have failed to find very few of a test list of new words, and those only the latest coined which have really not yet won an assured place in medical nomenclature. One curious omission is that of "eyestrain," a term which is surely worthy of a scientific definition. The work is especially rich in eponymic terms—a most commendable feature, since it is possibly these terms that drive the reader of modern medical books and journals to the dictionary. The illustrations, chiefly anatomical, are not too numerous, and are well executed; the only criticism we would offer is that many of them are too large, one picture taking up sometimes nearly an entire page when it would lose nothing in clearness if reduced at least one-half.

We have tried to point out the defects in the work rather than the excellences, since the latter are assumed to be present in every new book and new edition brought out under the guidance of this veteran medical lexicographer. The good points are numerous and striking, and they will doubtless serve to secure for this new work the same measure of popularity that the dictinnaries which have preceded it have enjoyed. Taken all in all—size, weight, binding, illustrations, definitions, and number of new terms—the Practitioner's Medical Dictionary is extremely satisfactory.

DIET IN HEALTH AND DISEASE. By JULIUS FRIEDENWALD, M.D., Clinical Professor of the Diseases of the Stomach in the College of Physicians and Surgeons, Baltimore, and JOHN RUHRÄH, M.D., Clinical Professor of Diseases of Children in the College of Physicians and Surgeons, Baltimore. Second Edition. Thoroughly Revised and Enlarged. Philadelphia and London: W. B. Saunders Co., 1906.

IN this second edition of their work, the authors have added some valuable material, notably in the chapters on "Salts," Klemperer's work on "Oxaluria," "Diet at Water Cures," and Prochownick's "Diet in Pregnancy and Pelvic Contraction." They have noted Chittenden's work and have added a revised list of recipes for ready reference. It is perhaps unfortunate that in making these timely additions to their work, the authors fail to relieve the book of much that is cumbersome and unessential in the text of the first edition. This would especially apply, for instance, to such chapters as that devoted to the diet in diabetes and that upon diet in phthisis. In the former considerable space is given to dietaries which, while applicable in Germany, are by no means so in England and America, and the space thus taken might, with considerable advantage to American readers, have been devoted to a more exhaustive consideration of the works of Chittenden and Folin, which tend to demonstrate that the old accepted standards of Voit, Von Noorden, and others, of the proteid requirements of a healthy individual, are probably considerably overestimated. The section on "Infant Feeding" and "Diet in Early Childhood" might also with advantage have been condensed. On the whole, however, this second edition will no doubt, like the first, fill a certain need, especially in training schools and as a ready reference book for the general practitioner.

GESAMMELTE BEITRÄGE AUS DEM GEBIETE DER PHYSIOLOGIE PATHOLOGIE UND THERAPIE DER VERDAUUNG. Von Dr. I. BOAS und Seinen Schülern. 1886-1906. Herausgegeben von Dr. I Boas. Specialarzt für Magen and Darmkrankheiten in Berlin. Zwei Bände. Mit zahlreichen Textabbildungen, Tabellen und 4 Tafeln. Band I. Band II. Berlin: Verlag von S. Karger, 1906.

THE one hundred and twenty-six separate articles on subjects connected with the physiology, pathology, and treatment of the digestive functions, comprised in these two volumes of over 700 pages each, represent the research work done by Boas and his pupils in the twenty years that the former's private polyclinic in Berlin has been in existence. Now that the stress of other work has forced him to give up active work in the clinic, Boas presents these contributions in collected form, because, he says, it appears to him to be a duty to give an accounting of what he and his assistants have accomplished during this time. It is indeed a series of records of intelligently directed effort well worthy of those who took part in it, and of the guiding mind that supervised the work. More than one-half of the articles are by Boas himself, and of the other authors many have attained prominence in the field of gastrointestinal medicine. The subjects dealt with naturally are most varied, and there is scarcely a phase of the subject in general that has not been made the object of research by this diligent coterie of workers, so that the two volumes form a work of reference whose importance can hardly be exaggerated. Its utility would have been greatly increased, however, if an index had been supplied.

A TEXT-BOOK OF HISTOLOGY. By FREDERICK R. BAILEY, A.M., M.D. Adjunct Professor of Normal Histology, College of Physicians and Surgeons, Medical Department, Columbia University, New York City. New York: William Wood & Co., 1906.

BUT few departures have been made in this volume from the plan of its first edition. The book has been improved in a general way by changes in some of the drawings and by the addition of several new diagrams. The short sections on Special Technique apnended to each chapter, the semi-diagrammatic character of most of the illustrations, and a happy accentuation of important elements in the text give it numerous practical advantages over other books of this kind. As in the first edition the elaborate section on the nervous system remains the chief feature of the work, which, with some revision and the embodiment of the more recent advances, contributes more than any other of its parts to make the book a useful one. The plan of this section is systematic and particularly adapted to teaching purposes. The author has been successful in simplifying by his treatment this difficult subject, noticeably in those chapters dealing with the fiber tracts of the cord. In this lies one of the chief merits of the book.

TUMORS, INNOCENT AND MALIGNANT; Their Clinical Characteristics and Appropriate Treatment. By J. BLAND-SUTTON, F.R.C.S. Fourth Edition. Chicago: W. T. Keener & Co., 1907.

THIS book is based on the primary fact that the diagnostic power is greatly increased by a combination of pathological and clinical knowledge, and this should be drawn not only from human, but from comparative sources, for in in many instances it is impossible to appreciate correctly the meaning of certain neoplasms without such information. Our views of tumors have so changed within recent years that numerous changes were rendered necessary in the text to bring the book up to date, and this has required the addition of many extra pages. Attention is called to the unsatisfactory classification of tumors which has hitherto prevailed and that adopted by the author, although capable of criticism, seems to fill the desired want. He divides neoplasms into six groups, those of the connective tissues, of the teeth, epithelium, and fetal membranes, teratomata, and cysts. The distinction between innocent and malignant growths is also well put—"the baneful effects of innocent tumors depend entirely on their environment but malignant tumors destroy life, whatever their situation." The book is entertainingly written and constitutes a very desirable presentation of the clinical characters of neoplasms with general indications as to their treatment.

Society Reports.

THE MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK.

Annual Meeting, January 21, 1907.

THE PRESIDENT, DR. THOMAS E. SATTERTHWAITE, IN THE CHAIR.

Report of the Committee on the Death of Dr. Glover C. Arnold.—Dr. ANDREW H. SMITH, Chairman.

Report of the Committee on the Death of Dr. Alfred W. Gardner.—Dr. ROBERT COLEMAN KEMP, Chairman.

Report of the Committee on the Death of Dr. Alexander E. MacDonald.—Dr. ADOLF MEYER, Chairman.

Experimental Studies in Arteriosclerosis.—Dr. OSKAR KLOTZ of Montreal, Canada, presented this paper, which was read by Dr. Adolf Meyer. The author stated that our conception of the pathology of arteriosclerosis had recently been so altered that much confusion existed at the present time as to what form or forms of arterial disease should be considered under that term. There were many who would limit the term to a single kind of lesion, while others were more liberal and used the appellation to include the great mass of arterial diseases which eventually led to a thickening of the vessel walls. The author of the term leaned towards using the word "arteriosclerosis" for all conditions of hardening of the arteries, and with that interpretation the older anatomists had agreed, reserving, however, the term "atheroma" for another distinct lesion. However, Virchow's description of endarteritis chronica deformans, as the commonest type of arteriosclerosis, had led to the adoption of these expressions interchangeably, and his views had recently found the most favor. In his own studies, Dr. Klotz said, he had given the wider use of the word, and had included under arteriosclerosis, as was formerly the case, all hardening of the arterial coats. The experimental production of arteriosclerosis in animals was of fairly recent origin. The first experiments undertaken were by direct injury, as crushing of an artery. In this way the experimenters had hoped to bring about sufficient change in the vessel walls to lead to aneurysm. They were disappointed in this, but instead of an aneurysm they found that certain local inflammatory changes with endothelial proliferation were produced. It had since been shown that in all cases where an artery was disturbed in its natural bed, thereby affecting the vasa vasorum, an inflammatory reaction was the result. Since the above mechanical experiments were made several other ways had been found to bring about the same results. The chronic endarteritis had been brought about by the intravenous inoculation of bacteria of low virulence. Thus, Dr. Klotz said, he had been successful in producing an endarteritis chronica deformans in the arch of the aorta, and sometimes in the abdominal portion by the injection of old laboratory stocks of the streptococcus or *Bacillus typhosus*. A true inflammation of the media (a mesarteritis) he had not succeeded in obtaining, except when the injury had been induced close to the vessel itself. In that case the inflammation of the surrounding tissue spread into the arterial wall.

The experimental endarteritis chronica deformans had histological characters quite similar to those in the human arteries. The lesion was composed of a heaping up, layer by layer, of the endothelial cells, while the connective tissue underneath the endothelium was also undergoing a proliferation. The result was that a white pearly plaque was produced, under which degenerative changes of a fatty character might develop in the deeper part of the intima. Pathological changes in the arteries had also been produced experimentally by the use of adrenalin, digitalin, nicotine, and barium chloride. In these cases it had been shown that the muscle cells in the middle zone of the media were primarily attacked, and, according to the intensity of the intoxication by these drugs, the cells either underwent a fatty degeneration or complete destruction. Along with the death of the muscle cells, the elastic fibers in the media were also affected, and, like the former, they either became fatty, or, with more severe intoxication, underwent necrosis. In each instance, the muscle fibers were primarily affected. This type of arterial disease, in which the media was first destroyed, was spoken of as Moenckeberg's arteriosclerosis. Not alone was the medial degeneration, with calcification, produced by means of certain drugs, but Dr. Klotz said he had also obtained it by the inoculation of the diphtheria toxin. This was important in demonstrating that the effects of diphtheria were not confined to nervous tissue and heart muscle, but that the muscular elements of the vascular walls were also attacked.

Some Diagnostic Features of Arteriosclerosis in Clinical Medicine.—Dr. LOUIS FAUGÈRES BISHOP, in this paper, said that the importance of arteriosclerosis must be judged by the symptoms which accompanied it. In itself a moderate degree of arteriosclerosis was of no importance to the individual. It was important only when considered in relation to its causes, and the possibility that their continuance might bring about serious functional and structural degeneration of blood-vessels which would endanger the functions of certain structures. To trace the steps in the process of development of arteriosclerosis and its symptoms it was necessary to begin with the physiology of the circulation. The organs of the circulation were composed of the heart, arteries, and veins, which consisted of soft, expansible vessels, capable, when relaxed, of holding three times as much blood as was ordinarily found in the body. For the proper circulation of this blood, the organs of the circulation were maintained in a uniform state of tension, which was altered in one place or another to vary the blood supply to meet the demands of the body. This general tonicity of the vessels was maintained by a central nervous influence that was constantly active. When for any reason this central influence was in excess, we had the hypertonicity of the blood-vessels. This immediately complicated the circulation by demanding a higher blood pressure, and tending to a hypertrophy of the heart. Under such circumstances, arteriosclerosis developed either as a conservative measure analogous to the hypertrophy of the heart, or perhaps also in a measure as a trophic change of central origin. The symptoms of arteriosclerosis were, therefore, the symptoms of hypertonia vasorum, with its irregularity of blood-vessel control, excepting in the case of very gross lesions, where there might be purely mechanical local results due to the blocking or rupture of a blood-vessel. This conception of arteriosclerosis, Dr. Bishop said, seemed to him to explain the local and general symptoms better than any theory that had regard only to the pathological anatomy. The influence of the nervous system in originating and maintaining a vicious tension in the circulation was second only in importance to the results of degenerative kidney disease, and of late years it had seemed to him that the cases of nervous origin were becoming even more frequent than those primarily of nephritic origin. Much was said about the strain of modern life, and it seemed that here was a point where we could put a finger upon a definite result of a too strenuous existence. Constant strain and worry brought about changes in the circulatory system which apparently led eventually to structural changes, to hypertrophy of the heart, and the subsequent secondary degeneration. The condition was found in women as well as in men, although men were more subject to the causes. Dr. Bishop said he had lately come to use the term chronic vascular overtone to describe a disease that had attracted the attention of the students of medicine for many years, and the true nature of which had always been a matter of speculation. It was ordinarily spoken of as high blood pressure, but in the light of his experience he thought that chronic arterial overtone would be a better name. Opposed to vascular

overtone, there was a corresponding condition of vascular undertone, which he had described in several papers under the name of constitutional low arterial tension. The recognition of the physiological fact of the existence of this constantly acting force between the nervous system and the vascular system would explain very beautifully many of the disorders of circulation found in functional and organic disease of the nervous system, and would point the way to the interpretation and treatment of many circulatory disorders hitherto misunderstood and considered incurable.

Visceral Arteriosclerosis.—Dr. Harlow Brooks, in this paper, stated that the visceral arteries were those of the "medium" class, as classified by the histologists, and were the trunks which had a thick and well-developed muscle coat. This heavy media was physiologically necessary, since the blood supply to these organs was alternately increased by the relaxation of the muscle, and decreased during the physiological resting stage by the local contraction of this coat. As a result of this delicately balanced function, even relatively slight changes in any of the walls of these very active vessels hindered or limited the possibilities in these directions. Thus, an alteration in the intima, even if it did not, as in most cases, also extend to the media coat, caused an appreciable alteration in the caliber of the vessel when it contracted or expanded. Most important of all, when the media or muscle coat became even slightly diseased, either by degenerative muscular alterations, by encroachments of interstitial hyperplasia, or by true inflammatory exudate, the physiological relaxation and contraction and the entire control of the nutritive vascular supply was interfered with, and the organ might, as a result, become chronically congested, or perhaps habitually anemic. In either case, the viscus became permanently damaged, and was no longer able to maintain properly its functions and its physiological balance in the interreactions of the body. A disturbance of this equilibrium led first to secondary changes in the immediately dependent organ, and perhaps finally to lesions of the general viscera. Furthermore, disease of the arterial walls in vessels of this class tended to alterations in the general blood pressure, probably in an attempt on the part of the body by an increase in pressure to balance the blood distribution, or to furnish a normal, requisite amount of blood for the functional activity of the diseased organ, especially if it be of great vital importance, as was the case with the heart or kidney. Elevation of the blood pressure, due apparently to local arterial disease, was particularly well illustrated in cases of arteriosclerosis or small contracted kidney, where the blood pressure was almost uniformly elevated, a fact for the full recognition of which we were chiefly indebted to Janeway. In concluding his paper, Dr. Brooks emphasized the following points: 1. The great frequency of visceral arteriosclerosis and its importance, particularly in internal medicine. 2. That it could be diagnosed in many cases, partly by exclusion, partly by its direct signs and symptoms, and partly by the results attending treatment. 3. That treatment was attended with great benefit in a very considerable number of cases, but it must first be based on a close study of the special etiology, on a thorough appreciation of the physiology of the diseased organs, and of the special idiosyncrasies of each instance; and, finally, on a correct diagnosis.

Arteriosclerosis in Diseases of the Eye.—By Dr. Wilbur B. Marple. (See page 421.)

Dr. Reynold Webb Wilcox said the subject under discussion was one of the most important that was before the student of internal medicine to-day. A good deal of work had been done in the line of experimental arteriosclerosis, as had been pointed out in the paper sent by Dr. Klotz, and some extremely valuable contributions to this subject had been made by Pierce of Albany. Although this work was still in an experimental stage, it could be assumed with a fair degree of safety that the changes that were thus produced in the walls of the arteries corresponded very closely to those that were observed clinically in the human subject. We knew that when an artery was injured, followed by secondary changes in the media, precisely the same changes took place as followed the administration of adrenalin or barium chloride. The alterations in the arterial walls were similar in both instances. In regard to the changes induced by pathogenic bacteria, that question was not yet accurately determined, and probably would require further experimentation. In reference to Dr. Marple's paper, the speaker said there was at least one point that could not be too strongly emphasized; namely, the importance of the ophthalmoscope as a diagnostic aid to the general practitioner. In speaking of so-called albuminuric retinitis, Dr. Wilcox referred to the inaccuracy of the term, as this form of so-called retinitis might occur without the presence of albumin in the urine, and *vice versa* there might be albuminuria without the occurrence of retinitis. In speaking of hypertonicity, which Dr. Bishop had emphasized in his paper in its relation to the question of arterial sclerosis, the speaker said that this question was not of recent origin, as high blood pressure had been recognized almost as long ago as the small red kidney of Bright. On the other hand, Dr. Bishop's presentation of the subject was worthy of our most careful consideration because of its great practical importance. In the light of our present knowledge, a more appropriate name for this form of kidney lesion would be chronic arterial nephritis, which it really was. It simply represented one feature of a general arterial sclerosis, and in dealing with the condition, removal of the kidney capsule, as had been recommended in some quarters, could not possibly do any good, however much might be claimed for the procedure in other conditions.

Dr. Robert C. Myles, in speaking of the nasal manifestations of arteriosclerosis, said that for many years he had occasionally met with a certain class of patients who gave a history of recurrent nosebleed, evidenced by very small clots, which, upon examination, were traced, not to erosions of the cartilaginous-septum, as was usually the case, but to the rupture of small blood-vessels on the turbinals or higher up in the nasal tract. At times, these small hemorrhagic extravasations became mixed with muco pus and degenerated, and gave rise to an offensive odor. The condition was usually seen in men who were high livers and of great nervous activity. It was invariably associated with evidences of a general high blood pressure, and at times was the forerunner of a fatal issue from arterial disease.

Dr. Adolf Meyer, in discussing arteriosclerosis of the nervous system, said that neurologists, instead of limiting themselves to the end results of arterial disorders, as they had long done, had at last reached the point where such disorders were studied during the process of their formation, or at least before the onset of the final results. In this field the work done by Fisher, Adler, Janeway, Brooks, Collins, and others might well be a matter of pride with the members of the profession in this city. It was scarcely a decade ago when apoplexy and senile dementia were practically the only neurological conditions thought of in connection with arteriosclerosis, but the more widespread influence of circulatory disorders upon the nervous system was now much more fully appreciated. In the timely recognition of these conditions, the easy methods for measuring the blood pressure had become a valuable routine, and the help of the ophthalmoscope would prove very valuable as the most direct means of inspection of a local vascular net.

Dr. Bishop, in closing, said it was only by recognizing hypertonia vasorum and its relation to the physiological tone of the voluntary muscles that we could in any way understand the beneficial effects of exercise, particularly the resistance exercises as advocated by Schott in the treatment of certain cardiac conditions dependent upon peripheral disease. The speaker said that when Schott's method was first

brought to his attention, he could not understand how the resistant movements had any particular value, and it was not until he had worked out the connection between the tone-maintaining influence of the voluntary muscles and the tone-maintaining influence of the circulatory system that it became clear to him. By these resistance exercises and by moderately severe out-of-door exercise the blood pressure was regulated. This fact he had frequently verified by clinical observation. Whether or not the structural changes in the blood-vessels could be removed he knew by actual observation that prolonged regulation of the circulation broke up the high pressure habit and led to a practical cure of hypertonia vasorum.

Dr. Marple, in reply to Dr. Wilcox, said that the term retinitis albuminurica was not used much by opthalmologists to-day. It was a term that had been introduced many decades ago, and had survived its usefulness. It had been well understood for a long time that it was really due to a vascular degeneration. Not infrequently we saw exquisite pictures of arteriosclerosis in the retina, and no albumin was found in the urine, yet time showed that we were dealing with a contracted kidney. In the retina we had a retinal sclerosis; in the kidney a renal sclerosis.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON PEDIATRICS.

Stated Meeting, Held February 14, 1907.

DR. GODFREY R. PISEK IN THE CHAIR.

A Case of Complete Alopecia Areata.—Dr. HENRY E. HALE presented a girl, fourteen years old, who noticed three years ago that the hair was falling out from the top of her head. This bald spot spread peripherally until the hair had all disappeared within four months. One month after the hair had disappeared from the scalp her eyebrows and eyelashes disappeared. These latter came and went a number of times Last November she noticed a return of her hair, which was very light and fuzzy, and was now coming back, although very slowly. There was no family history of syphilis, tuberculosis, or wasting diseases.

Dr. HENRY W. FRAUENTHAL believed congenital lues to be an etiological factor in this case.

A Case of Little's Disease.—Dr. WALTER B. JENNINGS presented a boy, six years old, with a condition the mother believed to be due to a difficult and protracted labor. When four years old he had an attack of spinal meningitis. He had been treated in Roosevelt Hospital for rachitis. He cried a great deal during the first year of life. The speaker had seen the child but once, and therefore the history obtained was very incomplete as yet.

Dr. JOHN HOWLAND believed the case to be, not one of Little's disease, but one of cranial hemorrhage occurring at birth. This same child had been presented to a medical society two years ago and then appeared as he now did. The mother had stated that after birth the child breathed badly, and artificial respiration had to be resorted to. He could not hold his head up when eight months old, and when eighteen months old he could not sit up without assistance. There was a free sensorium. The prognosis as regards the physical condition was bad, although his mental condition would always be good.

Dr. L. E. LA FETRA had seen the child when he had spinal meningitis, and at that time a great deal more attention was paid to the meningitis than to the previous history.

Dr. GODFREY R. PISEK said that the diagnosis of Little's disease could be thrown out in this case and without doubt the condition was due to a hemorrhage into the brain which occurred as the result of a prolonged and difficult labor.

A Case of Multiple Bone Tumors (Exostoses).—Dr. HENRY W. FRAUENTHAL presented a young girl who had a number of bone tumors scattered over the body, mostly affecting the flat and long bones, but not the skull.

Dr. SAMUEL LLOYD reported the case of a four-year-old child who fell upon both outstretched hands and developed what he then supposed to be a tuberculous dactylitis, starting in the metacarpal bones of the little finger on both sides. A few weeks later he was surprised to find both olecranons involved, and shortly after these tumors developed in other parts of the body; she had at least half a dozen of these exostoses. She finally died of sarcomatosis, with the characteristic cracked-eggshell tumors. They were not the characteristic osteosarcomata, but they spread and involved the different tissues. Many of these cases, such as presented by Dr. Frauenthal, he believed could be traced back to parentage.

A Case of Mycotic Carditis with Multiple Emboli and Extensive Gangrene of the Lower Extremities.—Dr. K. H. GOLDSTONE reported this case, which was mainly of interest on account of the severity or malignancy of the process, of its comparative rarity in childhood, and of its being somewhat atypical. The child was two and a half years old. The family history was negative. Since last May, when he had a second attack of pneumonia, he had not been well; he coughed, was pale, but the weight remained stationary. In November he suffered an attack of diphtheria, and since then the child was always ailing; his cough grew worse, the pallor increased, he played less but did not lose weight. Dr. Goldstone first saw the boy December 27 last. He had been acutely ill two days prior with cough, dyspnea, fever, and sweating. On examination he found a normal sized child, but pale, with an emphysematous chest, craniotabes, but without any marked bone lesions. There were sibilant and sonorous râles all over the chest; tubular breathing over the left apex and left lower lobe behind. There was emphysematous breathing. The heart was normal. The abdomen was slightly protuberant and soft. The liver and spleen were not felt. The temperature was 100.5°, pulse 110 and respiration 30. The skin was clean. The fingers were not clubbed. The throat was clear, the gums pale, and the child's demeanor was anxious. He believed the child to be suffering from a chronic or persistent bronchopneumonia, and for such treated him. On December 31 he found a purplish discoloration encircling both ankles, about three inches in width, not in separate spots, but one large area of staining. There was no swelling, but the joints were painful to the touch. There were no other spots of ecchymosis noted. The lungs then were clear, except for bronchial breathing behind. The heart was irregular, but there were no murmurs. The temperature was 101.5°, pulse 20 and respirations 30. On January 1 the ecchymoses had extended to middle of the leg and covered half the foot; these areas were swollen, exquisitely tender, but hard and cold. Heart was irregular, but there were no murmurs. On January 2 the ecchymoses had extended to the knees and covered the whole of the foot. The limbs were greatly swollen, cold and almost black. The scrotum and penis were swollen, purple and cold. On January 3 the child was semicomatose. The gangrene had extended half way up both thighs, which were black, cold and three or four times the size of a normal limb, with here and there blebs and areas of broken integument. Petechial spots about the size of a penny appeared over both cheeks. The scrotum was greatly enlarged, black and cold. The abdomen was relaxed. The temperature was 100.5°, pulse 160, respirations 60 The dyspnea was extreme. No urine had been passed for thirty-six hours, and the last specimen showed albumin and blood casts, but no free blood. On January 4 the condition remained about the same until 3 P.M., when the child went into a deep coma. There was no radial pulse. The breathing was of the Cheyne-Stokes type and, for the first time, a faint systolic murmur was heard at

the apex. The heart's action was irregular. Moist râles were heard over both chests. The mucous membranes were blanched, and petechial spots appeared on the eyelids. At 5 P.M. the child died peacefully. No autopsy was obtained and no bacteriological findings recorded, because of the objection of the family to permit even puncturing the skin.

Pigmented Spots in the Sacral Region of White and Negro Infants.—Dr. CHAS. HERRMAN read this paper. He said that these spots occurred in the dark-skinned races and had interested anthropologists for a very long time. In Japan, where 90 per cent. of the infants showed these spots, these macroscopical appearances were discovered over one hundred years ago. The first histological examinations of sections from the skin were made by Baetz in 1885. In 1903 Adachi published an exhaustive paper, in which the histological findings were very fully described. The conclusions were based upon the examination of a very large series of sections from Japanese infants and from apes. From his earlier investigations he came to the conclusion that the characteristic pigment cells which were found in the deeper layers of the corium in these cases, would be found also in white infants, even though they presented no visible spots. He therefore examined a series of sections from twenty-four white infants and found the characteristic pigment cells in ten. Upon the basis of these findings, he suggested that a careful examination of a large series of white infants would probably reveal the presence of visible spots in a few. Acting on this suggestion, a friend, Fujisawa, then attached to the clinic for diseases of children at Munich, found the spots in the fiftieth infant examined. In this he was fortunate, for the spots really occur in about 1 in 400. In 1906 Ebstein of Prague published a paper in which he stated that the spots had attracted his attention for many years. It was unfortunate that he had given to his paper the title "The Blue Spots in the Sacral Region and Other Mongolian Peculiarities in European Infants," for the peculiarities described were those of Mongolian imbecility. The sacral spots were to a certain degree characteristic of the Mongolian race insofar as they occurred in a very large percentage of their infants. The Mongolian imbeciles were so called by English writers from a certain superficial resemblance of their features to the Mongolian type. But they were not in the true sense of the word Mongolian. In this country, Ashmead, in 1905, published a paper on the spots as they occurred in dark-skinned races, but made no mention of their appearance in white infants. The spots occurred in a number of widely separated races in Japan and China, Java, Malay Peninsula, Hawaii, Greenland, etc., and were probably present in all dark-skinned races. They were also present in apes, and in them were of much larger size. During the last eighteen months Dr. Herrman had examined about 1,800 infants. The spots were present in five—that was, about 1 in 400. In all these the hair and iris were dark. In a series of negro infants examined in Dr. La Fetra's service at the Vanderbilt Clinic, the spots were present in 30 per cent. and were more distinct in those cases in which the parents were entirely dark skinned. The spots were most frequently found in the sacral, lumbar, and gluteal regions, and occasionally on the upper part of the back, shoulders, or the anterior surfaces of the extremities, but very rarely on the face; in one case they were found on the inner surface of the thigh. According to one author, they appeared as early as the fourth months of embryonal life. They were present at birth and sometimes became more distinct during the first few weeks; after that they grew fainter and disappeared at the end of the second year, and occasionally, when in an unusual situation, they persisted for a longer time. In white infants there was commonly a single spot; in negro infants several. Their size varied from a dime to the palm of the hand. They were circular, elliptical, or irregular in outline. In white infants they were of a grayish blue color, not unlike a tattoo mark; in negro infants there was often a more greenish tinge. They were not raised above the level of the skin, did not change in appearance on pressure, and the outline could sometimes be made more distinct by putting the skin on the stretch. There was no growth of hair on the surface and no indication of blood-vessels. On microscopical examination of the skin the coloring was found to be due to the presence in the deeper layers of the corium of large spindle or star shaped cells filled with dark brown pigment granules, not unlike those in the choroid. These cells were present in small numbers in about 40 per cent. of white infants, but only in one case in 400 were they in sufficiently large numbers and sufficiently closely grouped to produce a visible spot upon the skin. The spots were easily differentiated from hemorrhages and vascular or pigmented nevi by their characteristic situations, color, absence of hair, or blood-vessel formation, and by the fact that they were not raised above the surface, did not change on pressure, and tended to disappear at the end of the second year. The last point was worth noting, for as they occasionally occurred on the face the question of surgical removal might come up. Why the spots should occur with so much greater frequency in the sacral region was not known, but it was worth mentioning that this region was to a certain extent a point of least resistance, as was shown by the occurrence of developmental anomalies, spina bifida, dermoid cysts, and the other tumors. The fact that the spots were present in the infants of a large number of widely separated races, and the fact that the characteristic pigment cells were present on microscopical examinations in about 40 per cent. of white infants, would speak rather against their being a racial characteristic. The evidence in favor of their being considered stigmata of degeneration was also insufficient.

Dr. HERMAN SCHWARZ and Dr. GODFREY R. PISEK discussed the paper.

Dr. Charles Herrman closed the discussion.

The Surgical Treatment of Empyema.—Dr. SAMUEL LLOYD read this paper. It was now generally conceded that there was but one treatment for the cure of a purulent pleurisy, the immediate evacuation of the pus by some surgical procedure. It was a just criticism that these cases were not recognized earlier and not subjected to a more radical treatment as soon as the diagnosis was made, and this was frequently due to neglect of some of the diagnostic aids now available. Whenever a medical man had a case of pneumonia which did not resolve in the usual way, and particularly if there were evidences of pleuritic involvement, he should suspect a localized empyema, and he should take every possible means of determining whether or not pus was present and responsible for the continuance of the symptoms. Another condition for which these localized symptoms were mistaken was tuberculosis, and Dr. Lloyd had had fourteen or fifteen cases where the physicians had made the diagnosis of tuberculosis. Unless one had all the data necessary to make such a diagnosis definite, the question of empyema should be considered. One of the difficulties noticed was that clinicians depended upon needles of too small caliber to determine the presence or absence of pus in the pleural cavity. The pus in such a case was sometimes thick, filled with fibrin flakes, and would clog any needle except one of considerable size. The needle should be longer than the one usually employed. The syringe should be of considerable size, or, better yet, an aspirator should be employed. The *x*-ray was of value in making a diagnosis, and they had recently had two cases of interlobar pneumonia, and one of abscess of the lung, in which the diagnosis was made by means of the *x*-ray. He emphasized the fact that a fluid which macroscopically

might appear to be simply serous, microscopically might show the presence of a large number of pyogenic microorganisms, and these cases were just as much empyemas as those from which they withdrew the usual creamy pus, and should be operated upon as soon as the diagnosis was made. As to whether one should, at the time of making the exploratory puncture, take out more of the fluid than was necessary for pathological examination, or whether one should take out as much of the fluid as was possible, this to a certain extent depended upon the condition of the patient; experience and surgical judgment should be the controlling factors in determining whether an aspiration should be performed, or whether the operator should proceed at once to a more radical measure. In his series of cases he had but eighteen aspirations. Of these, two were cured and sixteen died. Dr. Lloyd said he favored the early aspiration of the pleural cavity. So soon as the physician was convinced or had a suspicion of fluid in the pleural cavity, if it was showing signs of becoming purulent, or if there was an unresolved pneumonia or tuberculosis, he would introduce a large sized exploring needle and withdraw a sufficient amount of fluid to submit to microscopical examination, and staining, for the presence of micrococci. If these were present, an aspirating syringe should be attached to the needle and all of the fluid withdrawn. Should severe attacks of coughing ensue, the withdrawal of the fluid should stop, and the opening be sealed. In doing this the whole chest should be prepared as though one intended doing a capital operation. If, in the course of the aspiration, it was determined that the lung was coming down and expanding to fill the chest cavity, the operator might be satisfied with the simple removal of the fluid. If, on the other hand, the lung did not expand, a more radical operation was indicated. In cases of emphysema, thoracotomy should be performed. In simple aspiration the best results were obtained in those cases where the pneumococcus was the cause. Thoracotomy should be performed in all cases where it was demonstrated that the fluid was purulent and the lung still capable of expansion. The question of resection of a rib must be determined, to a certain extent, by the condition of the fluid. If the microorganisms were not particularly virulent, and the adhesions of the lung were recent and not too dense to prevent expansion, and the intercostal space was sufficiently wide to allow the insertion of the drainage tube without compression, the probabilities were that the simple incision between the ribs would suffice. But, on the other hand, if these conditions did not exist, resection of the rib was essential. Dr. Lloyd had used incision and drainage only nineteen times; of these patients six were cured, two improved, and eleven died. Simple resection of the ribs had been performed forty-five times, with twelve patients cured, eighteen improved, and fifteen deaths. The problem was not simply one of the evacuation of the pus, but also of obliteration of the suppurating cavity. Dr. Lloyd's experience had convinced him that decortication of the lung as a method of closing old cavities, as suggested by Fowler and Delorme in 1893, had a comparatively small application. He had operated upon twenty cases by this method, in which seven were cured, five died, and five were not improved, and in three the operation had to be suspended because of hemorrhage. He had operated by the Schede-Estlander method five times, with one cure, three patients improved and one death. Dr. Lloyd believed that it was invariably better to make an elastic organ fill up the cavity which it should occupy than to attempt to make the inelastic wall fall in against the collapsed lung. Then followed a description of his method of operating; this will appear in the March *Annals of Surgery*. The anesthetic, in his opinion, should be ether, and the success of the operation depended very largely upon the proper regulation of the anesthetic. The patient should be completely anesthetized until the ribs had been resected and the operator was ready to incise the pleura. Then it was his rule to order that all anesthesia should cease at once, and before the pleura was opened. One reason for this was because occasionally they found that the fluid was evacuated very rapidly in spite of all attempts to control it, the intrapleural pressure being so great that it burst through the pleura as soon as the soft parts and the ribs had been removed; in these cases if the adhesions were recent the lung broke away from them, filled the pleural cavity, and at the same time a large amount of the anesthetic was inhaled. A more important reason for stopping the anesthetic was to allow the patient to recover gradually during the remainder of the manipulation. Sweeping the finger over the pleura caused the partially anesthetized patient to cough, and with each forced expiration the collapsed lung was seen to expand. This should be continued until the full expansion of the lung was obtained. Frequently it would be pushed out of the wound. Unless the patient was pretty well over the effects of the anesthesia, this procedure could not be carried out. There would be no response to pleural irritation under complete anesthesia, and consequently no cough. This was an essential part of the operation. The number of cases upon which his paper was based was 400. Of this number 171 were cured, 114 improved, and 115 died.

Dr. L. E. La Fetra did not agree with Dr. Lloyd in his statement that the empyema should be operated upon as soon as diagnosed. It had always seemed to him that the children did better if the operation was not done at the time of the beginning of the fever which started the empyema; it would be better to wait two or three days, when the temperature would be less. A small number of cases could be cured by aspiration alone, but this fact should not lead them to adopt this as a regular method of treatment for empyema. He thought that Dr. Lloyd's method of administering the anesthetic was a great advance in the management of these cases.

Dr. Herman Schwarz agreed with Dr. La Fetra in regard to the time for operating; not only did the empyema cause the temperature, but the presence of an active pneumonia as well, and children did not do so well in that phase of the disease. In Dr. Koplik's wards a rule they adhered to pretty closely was that a child under the age of two years did not require resection of a rib. They incised the intercostal space and drained the pus. They gave as little anesthetic as possible; in fact, after the skin and muscles were incised, the anesthetic was stopped. When the pleura was incised the child was practically out of the anesthetic.

Dr. Edward W. Peterson corroborated all that Dr. Lloyd had stated in his paper. The age of the child was an important prognostic factor. In children under the age of one year 75 per cent. recovered, no matter what treatment was adopted. The nature of the infection was another prognostic factor. If it was a pneumococcic infection, a large proportion of the cases would recover in recent cases by simple incision. The whole problem was in making the lung fit the cavity of the chest, or else making the chest cavity collapse to fit the lung.

Dr. Lloyd, in answer to Dr. La Fetra's criticism, said that one did not, as a rule, diagnose empyema quite so early, and when diagnosed the case had already passed the acute stage. He said he would not operate during the first two or three days of the disease. In some cases of empyema there would be present a pneumonia; if the case was left alone septic intoxication would rapidly become the prevailing symptom. It had been noticed that when such cases died it was from the empyema and not from the pneumonia. Consequently in his opinion it was more important to stop the intoxication than to increase the pneumonia by any manipulation of the lung, or the administration of an anesthetic. As a rule, the pneumonia met with was a resolving one. In many infants, because of the larger intercostal spaces, they drained better when

a simple thoracotomy was done; it was often not necessary to resect a rib. One of the superstitions in surgery was the insensibility of the pleura, and the reason why the pleura was supposed to be insensitive was because the patients were under the influence of an anesthetic. Let the patient be partially under an anesthetic, or completely out of it, then sweep your finger across the pleural surface, and there would result a cough, or a series of coughs. It had been demonstrated by Dr. Lloyd that a lung did not collapse, in spite of the fact that the opening in the chest wall was greater than the main bronchus. He related an experience he had in operating for an abscess in the lung, caused by a small tack being inhaled. He carried out the operation according to the rules he employed in operating for empyema, with the result that when the patient came out of the anesthetic, instead of a collapsed lung there followed an expanded one, and he could not then find the small abscess. In order to get expansion of the lung, the adhesions must first be broken up; then the pleura should be irritated in the partially anesthetized patient, who would begin to cough; with this cough there would be an attempt to force a way through a partially closed glottis. With each expiration, but not with each inspiration, the lung would come down. The point he wished particularly to emphasize was the mechanical part of this expansion of the lung.

Books Received.

While the MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

TEXT-BOOK OF ANATOMY FOR NURSES. By ELIZABETH R. BUNDY, M.D. 8vo, 252 pages, illustrated, muslin. P. Blakiston's Son & Co., Philadelphia. Price, $1.75.

WOMAN. By MYER SOLIS-COHEN, A.B., M.D. 8vo, 469 pages, illustrated, muslin. The John C. Winston Co., Philadelphia.

THE PRACTICAL MEDICINE SERIES. Under editorial charge of Gustavus P. Head, M.D. Volume X, Series 1906, 12mo, 250 pages, illustrated, muslin. The Year Book Publishers, Chicago.

PRACTICAL DIETETICS. By ALIDA FRANCES PATTEE. Fourth edition, 12mo, 359 pages, illustrated, muslin. A. F. Pattee, Publisher.

PLASTER OF PARIS AND HOW TO USE IT. By MARTIN W. WARF, M.D. 8vo, 88 pages, illustrated, muslin. Surgery Publishing Co.

THE CHEMICAL INVESTIGATION OF GASTRIC AND INTESTINAL DISEASES. By VAUGHAN HARLEY, M.D., Edin., and FRANCIS W. GOODBODY, M.D., Dubl. 8vo, 261 pages, muslin. Longmans, Green & Co., New York.

ORGANIC AND FUNCTIONAL NERVOUS DISEASES. By M. ALLEN STARR, M.D., Ph.D., LL.D., Sc.D. Second edition, thoroughly revised, 8vo, 816 pages, illustrated, muslin. Lea Brothers & Co., New York.

THE PRACTICE OF OBSTETRICS. By American Authors. 8vo, 1,807 pages, illustrated, muslin. Lea Brothers & Co., New York.

TRANSACTIONS OF THE AMERICAN OPHTHALMOLOGICAL SOCIETY. Forty-second annual meeting, Vol. XI, Part I, 8vo, 247 pages, illustrated, paper. Published by the Society, Hartford.

DIAGNOSE UND THERAPIE DER ANÄMIEN. Bearbeitet von Dr. JOSEPH ARNETH. 4to, 208 pages, paper. A Stuber's Verlag, Wurzburg.

EXPERIMENTAL ZOOLOGY. By THOMAS HUNT MORGAN. 8vo, 454 pages, illustrated, muslin. The Macmillan Co., New York. Price, $2.75 net.

INTERNATIONAL CLINICS. Edited by A. O. J. KELLY, A.M., M.D. 8vo, 322 pages, illustrated, muslin, Volume IV, 16th Series, 1906. J. B. Lippincott Co., Philadelphia.

TRANSACTIONS OF THE AMERICAN SURGICAL ASSOCIATION. Volume XXIV. Edited by RICHARD H. HARTE, M.D. 8vo, 501 pages, illustrated, muslin. William J. Dornan, Philadelphia.

MANUEL DE GYNÉCOLOGIE PRATIQUE. Par J. BAROZZI. 12mo, 813 pages, illustrated, muslin. Vigot Frères, Editeurs, Paris.

Surgical Suggestions.

Injuries About the Elbow Joint.—When the *x*-ray is not available the following plan of procedure, suggested by Gerster and described by Dawbarn, may prove of service in facilitating the diagnosis of injuries about the elbow joint when there is much swelling: The patient having been anesthetized, an Esmarch elastic bandage is slowly and firmly applied from the hand up the forearm and over the elbow to the arm-pit. This is left on for about fifteen minutes and then removed from below upward, the final turns upon the upper arm being allowed to remain. The removal of the edema in this manner permits of the recognition of a fracture or dislocation, and this having been accomplished, the upper turns of the bandage are removed.—*International Journal of Surgery.*

Writers' Cramp.—The following plan was successfully used by Hartenberg to cure a case of writers' cramp: The patient, who had suffered from the condition for about fifteen years, was instructed to apply a rubber tube firmly around the biceps for twenty minutes at a time every morning and evening. At the end of a few weeks the patient had almost entirely recovered.—*Archives de Neurologie.*

Indications for Tracheotomy.—James Berry gives the following advice in regard to determining whether or not tracheotomy is necessary. Two points that guide in the decision are the cyanosis and the recession of the chest-walls. Cyanosis alone is not sufficient indication for the operation. It may be due not so much to laryngeal obstruction as to obstruction within the chest itself. In diphtheria, for example, there may be much blueness of the face from pneumonia even though the larynx be quite free from obstruction. Tracheotomy in such a case as this would be worse than useless. Recession of the chest-wall is a very valuable indication for the operation. When you see the supraclavicular fossæ receding deeply at every attempted inspiration, when the lower ribs and the epigastrium are sucked violently inwards each time the child tries to breathe, then the dyspnea is due to an obstruction in or near the larynx, and relief to the dyspnea is urgently demanded. The dyspnea being severe and progressive, dyspnea and the recession of the chest-walls indicating laryngeal obstruction, tracheotomy is indicated, if intubation cannot be performed.—*The Clinical Journal.*

Rectal Feeding.—Becker proceeds in this way: The number of meals in twenty-four hours should not exceed two, one meal in the morning and one late at night. One hour before the morning meal a suppository of opium and belladonna is introduced, and then an hour later the rectum is carefully cleansed with lukewarm water to which some salt is added—it need not be physiological salt solution. The temperature of the cleansing water should range—like the other things introduced into the rectum—from 42 to 45 degrees centigrade. It should be introduced into the rectum with moderate force in moderate quantities, say 150 c.c. at a time, and the tube should remain in the rectum for the return of the soiled water. A good sized rectal tube should be used for the cleansing, and the tube should have a rather wide lumen, and should not be too flabby. The introduction and the letting out of the water are repeated until the water returns absolutely clean. Then the tube is turned and pushed in and out several times to ascertain and insure that all the water, or at least as much as possible, has left the colon and rectum. Now the patient is given a short time of rest, say fifteen or twenty minutes, after which the rectal meal is introduced. The same rectal tube is used and is introduced about 15 c.m., and then the meal, 200 c.c., at most 250 c.c., is slowly introduced at a temperature of from 42° to 45°.—*Wisconsin Medical Journal.*

Poison Ivy.—Since there is apparently much doubt as to the best method of treatment of the dermatitis of rhus poisoning, the information may be of interest that in the powdered crude sulphur of the stores we possess a remedy everywhere obtainable and usually promptly successful. Its application is best made by mixing it with a little water, and perhaps a few drops of glycerin, this to be rubbed over the affected area two or three times a day. Next best is its use mixed with just sufficient lard to bind it. As to the time of activity of the poison I remember a patient who infected himself in early spring before appearance of the leaves by tearing out roots in a clearing for garden culture.

C. G. AMENDE, M.D.

New Instruments.

A THERMESTHESIOMETER AND A POCKET ESTHESIOMETER

By FREDERICK PETERSON, M.D.,

NEW YORK.

THE temperature sense is generally tested by the application of test tubes containing hot and cold water, and such a method is, as a rule, sufficiently accurate for the practical and gross determination

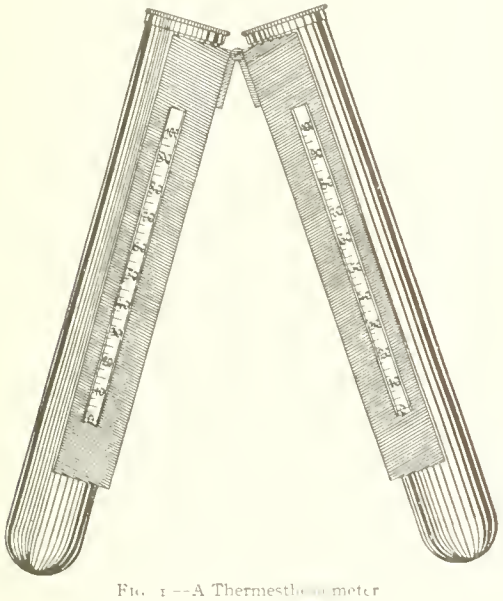

FIG. 1.—A Thermesthesiometer.

of the loss of this sense in, for instance, a case of syringomyelia. But I have long felt that some more precise instrument should be used for this purpose, since the more we study the skin and its innervation the more important does it become from the neurological standpoint. I need only allude to the fact that at one time we spoke of general sensibility as one of the five senses, whereas now we know that there are four or five, perhaps more, skin-senses, such as touch, heat, cold, pain, not to speak of other forms of general sensation, like pressure, muscle-sense, space-sense, tickling, etc. Now we have, too, a new and wonderful relation of the skin to psychic processes, as revealed by the electric psychometer; and we have the new studies of Head, Rivers, and Sherren on the various avenues by which the epicritic and protopathic systems of sensory fibers reach the central nervous system. In studying the temperature sense it is found that certain points on the skin feel cold and others warm impressions, that these points are separate, and that they are unequally distributed over the surface of the body. For instance, on the legs one finds areas of several square centimeters where neither cold nor heat is perceived. Furthermore, cold points are in general more numerous over the body than warm points. Another interesting phenomenon is that if a cold point be touched by an object heated above 45° C. a sensation of cold is produced. To the end, therefore, that more exact measurements of the temperature sense may be made, I have devised the thermesthesiometer shown in the illustration. It consists of two metal test tubes with covers, united at one end by a hinge, so that it may be opened like a compass when in use, in order to insulate each tube from the other, and closed when replaced in its case. Each tube has attached to it a thermometer inclosed in wood, but in contact with the metal of the tube on one side, so that the temperature of each may be accurately known at any time. The instrument has been constructed in the best manner with carefully tested thermometers by M. Sendtner, maker of instruments of precision, Schillerstrasse 22, Munich, Germany, whose American agent is Eimer & Amend, New York.

In addition to the thermesthesiometer, Sendtner has constructed for me the convenient pocket esthesiometer shown in the accompanying illustration, with a needle, blunt point, and camel's hair brush which slide back into the handle on the principle of some of the metal lead-pencils.

4 WEST FIFTIETH STREET.

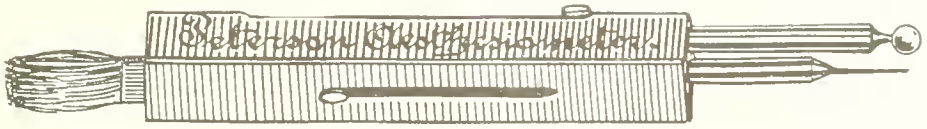

FIG. 2.—Pocket Esthesiometer.

Therapeutic Hints.

Sore Nipples.—These may be painted with a 4 per cent. solution of silver nitrate, or an ointment having the following composition may be applied:

℞ Bals. Peruvian 3i
Ungt. tq. rosæ.
Lanolini ..... āā ℥ss

Epidemic Influenza.—

℞ Phenacetine ..... gr. iii
Quin. sulphat ..... gr. iv
Pulv. ipecac et opii ..... gr. ss
Ext. aconiti ..... gr. ⅛

M. et ft. pil. No. 1. S.: One pill four times a day.

Migraine.—Carron de la Carrière recommends pills of extract of Indian hemp, each containing 0.015 of the drug. These are given every night for thirty days, at the end of which time, if no improvement has resulted, the dose is increased to two pills. The remedy may be used over long periods without danger. During acute attacks the forehead is rubbed with the following:

℞ Menthol 5.0
Chloroform 5.0
Methyl salicylate 5.0
Lanolin 30.0

—*Presse Médicale.*

Scabies.—

℞ Sodii carbonat ..... ℥i
Sulphuris ..... ℥iii
Glycerini ..... ℥vi
Gum. tragacanth ..... gr. xv

The patient rubs himself with ordinary soap for half an hour, then takes a bath, followed by brisk friction with the above mixture. The following day and for two or three days afterward the patient takes a starch bath (one pound of starch for each bath), and powders himself with the same substance.—*Medical Press.*

Opium Habit.—For the mental and physical depression Ringer recommends:

℞ Tr. capsici ..... ℥iv
Pot. bromid ..... ℥iv
Spt. ammon. aromat ..... ℥iiiss
Aq. camphoræ ..... ℥vi

Sig.: A dessertspoonful several times daily as required.

Menorrhagia.—

℞ Acid. gallici ..... ℥ss
Acid. sulphurici dil.
Tr. opii deod ..... āā ℥i
Infus. rosæ comp ..... ℥iv

Sig.: A tablespoonful every four hours.

—BARTHOLOW.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

UNIVERSITY OF THE STATE OF NEW YORK.

January 29-February 1, 1907.

The candidate is required to answer any 10 of the questions on each paper, but no more.

ANATOMY.

1. Locate and define (a) odontoblasts, (b) the ductus venosus, (c) the vesiculæ seminales.
2. Describe the arrangement of the bones of the ear.
3. Mention and describe the various forms of epithelial cells.
4. Describe microscopically (a) bone, (b) cartilage.
5. What is unstriped muscular tiber and where in the body is it found?
6. Describe the popliteal artery and give its branches.
7. What are ductless glands? Name the important ductless glands.
8. Describe a spinal nerve.
9. Give the minute anatomy of the skin.
10. Describe the appendix vermiformis and give its topography.
11. Give the origin, insertion, action and nerve supply of *one* of the following muscles: pectoralis major, levator ani, internal oblique.
12. Describe the superior petrosal sinus.
13. Give the gross anatomy of the tongue.
14. Describe the ovaries and give their relations.
15. What anatomic parts are normally found in the left hypochondriac region?

PHYSIOLOGY AND HYGIENE.

1. Describe bones as to varieties and functions. Give the general structure of bone.
2. What constitutes the lymphatic system and what forces are concerned in the circulation of the lymph?
3. Describe the controlling forces that regulate the circulation of the blood in (a) the arteries, (b) the capillaries, (c) the veins.
4. State the functions of the medulla oblongata.
5. Give the physiological mechanism of the valves of the heart.
6. Compare expired air with inspired air. What is (a) external respiration, (b) internal respiration?
7. Describe micturition. What mechanism serves to keep the urine in the bladder until it is voluntarily voided?
8. State where in the body *each* of the following substances is found and mention the special purpose served by each: (a) ptyalin, (b) pepsin, (c) glycogen, (d) trypsin.
9. Give all the causes of (a) contraction of the pupil, (b) dilatation of the pupil.
10. Mention the functions of the facial nerve and state the effects of its complete paralysis.
11. What kinds of contamination does the presence of *each* of the following substances in drinking water indicate: (a) nitrites and nitrates, (b) excess of chlorin? Give the causes of hardness of water.
12. Describe the best method of constructing a house drain.
13. What special measures of prophylaxis may be best employed against (a) typhoid fever, (b) yellow fever, (c) malarial fevers, (d) rabies?
14. Describe the best method of heating and ventilating a hospital ward.
15. How may milk be adulterated and how may it be contaminated with infectious elements?

CHEMISTRY.

1. Define destructive distillation, smelting, normal salts.
2. Name *two* monads, *two* dyads and *two* triads. Illustrate each in a graphic formula.
3. Describe the metric system of weights and measures and give the practical equivalent of each unit in Troy weight.
4. Give the uses and the chemical properties of phosphorus and mention any peculiarity of phosphorus in its relation to oxygen.
5. What constitutes hard water? How may the presence of albuminoid matter in water be recognized?
6. Give the chemical properties of ozone.
7. Name 10 principal elements chiefly concerned in the chemical changes taking place in life and describe the preparation of *one* of them.
8. Describe the preparation and give the properties of chlorin. On what important chemical feature does the useful application of chlorin depend?
9. Give the percentage composition of normal urine as to water, urea, uric acid, organic matter, and sodium chlorid.
10. What is electrolysis? State the ionic theory.
11. Give the chemical features of disinfection.
12. Mention the general properties of organic compounds.
13. What are hydrocarbons? Give the name and the formula of one important hydrocarbon.
14. Describe a method (laboratory or otherwise) of making alcohol (ethyl). What is the percentage of alcohol in (a) porter, (b) port wine, (c) champagne?
15. Describe the preparation and state the uses of cyanogen.

SURGERY.

1. Give the symptoms and the treatment of actinomycosis.
2. Mention the most common sites of epitheliomata.
3. Mention *three* operations on the stomach. Describe *one* of these operations and give the indications for its performance.
4. Give a classification of complete fracture according to (a) line of separation, (b) mode of production, (c) number of fractures present.
5. What are the immediate and the remote effects of a fracture-dislocation in the lower dorsal region?
6. What tumors occur in bone?
7. Give the treatment of hip joint disease in children.
8. Give the predisposing and the exciting causes of aneurysm.
9. What operative measures are applicable in the treatment of stone in the female bladder?
10. What is meant by secondary suppurative inflammation? Give the most frequent sources of secondary suppurative inflammation of the abdominal wall.
11. Give the treatment of an injury of the rectum involving the peritoneum.
12. What are the specific diseases of the vulva? Describe *one* of these diseases and give treatment.
13. Describe convergent strabismus and give its surgical treatment.
14. Give the symptoms of syphilitic rhinitis in the newborn.
15. Describe the pediculus pubis and mention the symptoms to which it gives rise. Give treatment.

OBSTETRICS.

1. Give a brief description of the physiology of reproduction.
2. Describe the liquor amnii and state its functions.
3. What pathological conditions of the internal organs of generation are liable to cause abortion? Give reasons.
4. Give the causes and the treatment of umbilical hemorrhage in the newborn.
5. Give the prognosis and the management of a face presentation.
6. Describe the effects of syphilitic infection on childbearing.
7. Mention the factors that affirmatively determine pregnancy between the third and the fourth month.
8. What is understood by premature artificial delivery? Mention the conditions that justify this procedure.
9. Give the treatment of retrodeviation of the uterus when it complicates pregnancy.
10. Give the technique of catheterization of the female.
11. Make a diagnosis of tubal pregnancy. State the dangers of tubal pregnancy.
12. Describe phlegmasia alba dolens and give the treatment.
13. Give the symptoms of pelvic abscess. Through what channels may pelvic abscesses drain?
14. Define vaginismus. Give the etiology and the treatment of vaginismus.
15. Give a technical description of the operation of craniotomy.

It is proposed in this department to publish from time to time the examination papers of the various State Boards, in order that a candidate may become familiar with the character of the examination and so in some measure free himself in advance from the nervousness and dread which the unknown inspires. In furtherance of the same object answers to some of the questions will be published in order to show the candidate what the examiners expect of him. Not all the questions of all the papers will be so treated, for the answers to many, especially in the anatomical papers, are obvious or can be found in the index of any textbook on the subject; the answers to other questions, especially in the surgical papers, must sometimes be omitted because of the space they would demand. The candidate for a medical license will not find in these answers a short and easy road to success in the examination, for he is not likely to meet the same questions in the papers placed before him by the examiners. The object of publishing the questions and answers is only, as noted above, to acquaint the candidate with the general character of these examinations and to inspire him with confidence in the result of his trial.

PATHOLOGY AND DIAGNOSIS.

1. What pathological changes occur in (a) tumefaction, (b) hypertrophy, (c) induration, (d) calcification?
2. Describe the bacillus of tuberculosis and give a method of demonstrating the same.
3. Mention some of the structural tissue changes caused by pyrexia.
4. What changes occur in the red blood corpuscles in progressive pernicious anemia?
5. Describe a method of making a bacteriological diagnosis in diphtheritis.
6. Under what pathological conditions may casts be found in the urine? Describe *two* varieties of casts.
7. Give the macroscopic and the microscopic appearance of pus.
8. Describe the skin lesions occurring in psoriasis.
9. Mention the pathological conditions that may arise from the presence of calculi in the gall-bladder.
10. Mention the changes that may occur in the nervous system as a result of syphilis.
11. What muscles are involved in the paralysis following lesions of the musculospiral nerve?
12. Describe a test meal and give the method of its use.
13. Describe the onset and the course of ophthalmia neonatorum.
14. Give the incubation period of (a) scarlatina, (b) measles, (c) variola, (d) varicella, (e) rötheln. Give the clinical history of *one* of these diseases.
15. Mention *three* pathological conditions the local symptoms of which are manifested in the epigastric region.

THERAPEUTICS, PRACTICE, AND MATERIA MEDICA.

Questions prepared by the Board of Examiners representing the Medical Society of the State of New York:

1. Give the therapeutic uses of lobelia.
2. Give the physical signs of aortic obstructive lesions of the heart.
3. Give the physiological action of digitalis on the heart and on the kidneys.
4. Define and describe iodism.
5. Give the treatment of acute lobar pneumonitis.
6. Mention the official preparation of strophanthus. State the dose of this preparation and describe its physiological effects.
7. Give the therapeutic uses of sanguinaria.
8. Give the diagnosis and the treatment of gonorrheal rheumatism.
9. Mention *five* official preparations of senna and state the dose of each.
10. Describe the therapeutic uses of sulphur.
11. State the period of incubation in hydrophobia. Describe the prophylaxis in hydrophobia.
12. What preparation of apomorphin is used medicinally? Mention the doses of this preparation and state for what it is employed.
13. Mention the class of acids administered to acidify alkaline urine.
14. Give the signs and the symptoms of intestinal perforation in typhoid fever.
15. State the dose of (a) liquor potassii arsenitis, (b) liquor sodii arsenatis.

ANSWERS TO STATE BOARD EXAMINING QUESTIONS.

UNIVERSITY OF THE STATE OF NEW YORK.

January 29 to February 1, 1907.

PHYSIOLOGY AND HYGIENE.

1. Bones are described as: (1) *Long bones*, consisting of a shaft (which is hollow), and two extremities; examples, humerus, tibia, metacarpals. (2) *Short bones*, which are compressed, short and spongy in structure, except on their surfaces; examples, the bones of the carpus and tarsus. (3) *Flat bones*, consisting of broad, flat plates of bone inclosing some cancellous tissue; examples, parietal, scapula. (4) *Irregular bones*, consisting of compact tissue externally, and cancellous tissue internally, are such as cannot be grouped under one of the preceding divisions; examples, vertebræ, ethmoid.

The *functions* of bones are: (1) for protection (chiefly the flat bones); (2) for muscular attachments (chiefly the long bones); (3) for support of the body (chiefly the long bones); (4) for locomotion and motion (chiefly the long bones); (5) for strength (chiefly the short bones); (6) to maintain the shape and outline of the body.

2. The lymphatic system consists of: lymphatic glands, lymph vessels, perivascular lymph spaces, the lymph canalicular system, the pericardial, pleural, peritoneal, and synovial cavities, and the lacteals.

The forces concerned in the circulation of the lymph are: (1) The pressure of the blood in the blood-vessels; (2) thoracic aspiration; (3) muscular contractions of the voluntary muscles; (4) contractions of the intestine; (5) the action of the valves in the lacteals and lymphatics.

3. The circulation of the blood is regulated in (a) *the arteries*, by: (1) the elasticity and tone of the arteries, (2) the force and frequency of the cardiac contractions, (3) the resistance in the capillaries; (b) in the *capillaries* it is regulated by: (1) the action of the heart, (2) the action of the arteries; (c) in the *veins* it is regulated by: (1) the action of the heart, (2) aspiration of the thorax, (3) the contraction of the muscles, and (4) slightly by the valves in the veins.

4. The functions of the medulla oblongata are: (1) It is a conductor of nervous impulses or impressions from the cord to the cerebrum, from the brain to the spinal cord, also of coordinating impulses from the cerebellum to the cord; (2) it contains collections of gray matter which serve as special nerve centers for the following functions or actions: respiration, salivary secretion, mastication, sucking, deglutition, speech production, facial expression; it also contains the cardiac and vasomotor centers.

6.

	Expired Air.	Inspired Air.
Oxygen	16.6 per cent.	21 per cent.
Nitrogen	79 per cent.	79 per cent.
Carbon dioxide	4.4 per cent	0.04 per cent
Other gases	Often present.	Rare.
Watery vapor	Saturated.	Variable.
Temperature	That of body.	Variable.
Volume	Diminished.	Varies.
Bacteria	None.	Always present
Dust	None.	Always present.

(a) External respiration is the interchange that takes place between the blood and the gases in the lungs; (b) internal respiration is the interchange that takes place between the blood and the tissues of the body.

7. The urine is kept in the bladder by the sphincter vesicæ and by the muscular and elastic fibers of the urethra.

8. (a) *Ptyalin* is found in the saliva; it changes starch into dextrin and sugar; (b) *pepsin* is found in the gastric juice; it changes proteids into proteoses and peptones in an acid medium; (c) *glycogen* is found chiefly in the liver and the muscles, also in the white blood corpuscles, and in the placenta; (d) *trypsin* is found in the pancreatic juice; it changes proteids into proteoses and peptones, and afterwards decomposes them into leucin and tyrosin; it acts in an alkaline medium.

9. (a) The pupil *contracts*: (1) when stimulated by light; (2) on stimulation of the third nerve; (3) on paralysis of the cervical sympathetic; (4) when the eye is accommodated for near objects; (5) during sleep; (6) through the action of certain drugs, called myotics, such as opium, and the local influence of physostigmine; (7) when the eyeball is turned inwards. (b) The pupil *dilates*: (1) on removal of the stimulus of light; (2) on paralysis of the third nerve; (3) on stimulation of the cervical sympathetic; (4) when the eye accommodates for distant objects; (5) in deep chloroform narcosis; (6) in dyspnea; (7) under the influence of certain drugs, called mydriatics, as atropine; (8) under the influence of pain, or fear.

10. The facial nerve is the motor nerve of the muscles of expression, also of the platysma and the buccinator; it also supplies the muscles of the external ear, the stylohyoid, and the posterior belly of the digastric. Through the chorda tympani it is a nerve of taste and a vasodilator of the vessels of the submaxillary and sublingual glands.

"When it is paralyzed, the muscles of the face being all powerless, the countenance acquires on the paralyzed side a characteristic, vacant look, from the absence of all expression; the angle of the mouth is lower, and the paralyzed half of the mouth looks longer than that on the other side; the eye has an unmeaning stare, owing to the paralysis of the orbicularis palpebrarum. All these peculiarities increase the longer the paralysis lasts, and their appearance is exaggerated when at any time the muscles of the opposite side of the face are made active in any expression, or in any of their ordinary functions. In an attempt to blow or whistle, one side of the mouth and cheeks acts properly, but the other side is motionless, or flaps loosely at the impulse of the expired air; so, in trying to suck, one side only of the mouth acts; in feeding, the lips and cheek are powerless, and, on account of paralysis of the buccinator muscle, food lodges between the cheek and gums." (Kirkes' *Physiology*.)

11. (a) The presence of nitrates and nitrites denotes contamination from nitrogenous organic matter of animal origin; (b) the presence of excess of chlorin denotes organic impurity of animal origin.

Hardness of water is caused by the salts of calcium and magnesium; usually the bicarbonate or sulphate, but sometimes the chloride, phosphate, or nitrate.

15. Milk may be adulterated by the addition of water (clean or dirty), by skimming, by the addition of coloring matters or preservatives, and by the addition of solid substances, such as sugar, flour, etc.

Milk may be contaminated with infectious elements by being obtained from infected cows, by being diluted with water containing disease germs, by the cans, containers, vessels, etc., being contaminated with dirty water; through carelessness in handling by persons who are infected.

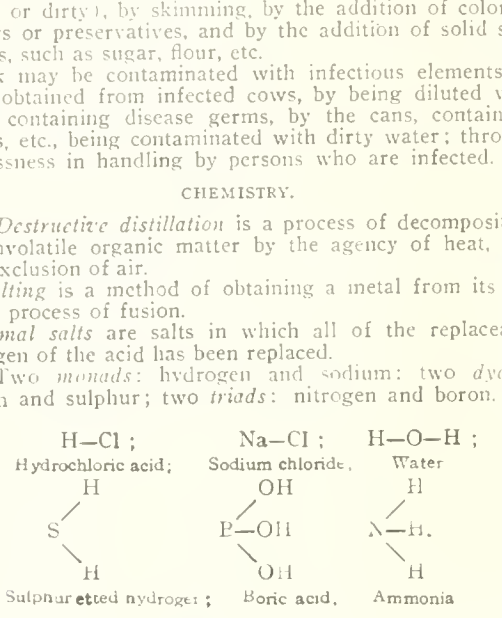
CHEMISTRY.

1. *Destructive distillation* is a process of decomposition of nonvolatile organic matter by the agency of heat, and with exclusion of air.

Smelting is a method of obtaining a metal from its ore by the process of fusion.

Normal salts are salts in which all of the replaceable hydrogen of the acid has been replaced.

2. Two *monads*: hydrogen and sodium: two *dyads*: oxygen and sulphur; two *triads*: nitrogen and boron.



4. The chief uses of phosphorus are in making matches, rat paste, and phosphor bronze. It is also used in medicine in cases of osteomalacia, rickets, and as a nerve tonic.

The chemical properties of phosphorus are: chiefly its readiness to enter into combination with oxygen; it is a reducing agent; it is not acted on by HCl or by cold H_2SO_4; it is oxidized by hot H_2SO_4, and by HNO_3.

5. Hard water is a water containing an excess of calcareous salt. (See above, Physiology, 11.)

6. Ozone is a strong oxidizing agent; it oxidizes nearly all metals in the presence of moisture; it decolorizes indigo and other pigments of organic nature; it is but slightly soluble in water.

7. Carbon, hydrogen, nitrogen, oxygen, iron, chlorine, sodium, potassium, calcium, sulphur.

Hydrogen is prepared by the action of zinc on dilute sulphuric acid:

$$Zn+H_2SO_4=ZnSO_4+H_2$$

8. Chlorine is prepared by the action of hydrochloric acid on manganese dioxide:

$$4HCl+MnO_2=MnCl_2+2H_2O+Cl_2$$

It is an active disinfecting and bleaching agent in the presence of moisture. It acts by decomposing the water, the nascent oxygen thus liberated attacks the odorous or coloring substance. Chlorine will not bleach a dry substance.

9. Water, 95.00 per cent.; urea, 2.80 per cent.; uric acid, 0.06 per cent.; organic matter, 3.75 per cent.; sodium chloride, 0.80 per cent.

10. Electrolysis is the process of electrical conduction accompanied by the separation of the constituents of the electrolyte; or the decomposition of a chemical compound by passing an electric current through it. The primary products of electrolysis are called ions; those which separate at the positive electrode or anode are called anions; those which separate at the negative electrode or cathode are called cations. A solution of sodium chloride contains NaCl, but it also contains the cation Na and the anion Cl; and the action of the electric current is to separate these ions (which are already liberated) at the respective electrodes. It is supposed that the hydrogen and metallic ions are charged with positive electricity, and the hydroxyl and acid-residue ions are charged with negative electricity; hence the former are attracted to the cathode and the latter to the anode.

11. Chemical disinfectants act in virtue of their power to form definite chemical compounds with the bacteria which are responsible for the infection. The bacteria are thus rendered harmless. In order to accomplish this the disinfectant must come in direct contact with the bacteria, and in the combination thus effected both bacteria and disinfectant change their chemical properties.

12. Organic compounds may be either gases, liquids, or solids (either crystalline or amorphous); may be either volatile or nonvolatile; may be either colorless, tasteless, odorless, or have any variety of these qualities; they are changed by heat and chemical reagents with a readiness which is directly proportionate to their complexity.

13. Hydrocarbons are chemical compounds consisting of carbon and hydrogen only. *Example*, Methane, CH_4.

14. Ethyl alcohol can be formed synthetically from calcium carbide, water, and hydrogen. Thus (1) calcium carbide and water form acetylene:

$$CaC_2+2H_2O=CaH_2O_2+C_2H_2$$

(2) Acetylene vapor and water form aldehyde:

$$C_2H_2+H_2O=CH_3.CHO.$$

(3) Aldehyde and nascent hydrogen form alcohol:

$$CH_3.CHO+H_2=CH_3.CH_2OH$$

(a) Porter, 4 to 6 per cent.; (b) port wine, 19 to 25 per cent.; (c) champagne, 8 to 12 per cent.

15. Cyanogen is prepared by heating mercuric cyanid:

$$2\ Hg\ (CN)_2 = 2\ Hg + 2\ (CN)_2$$

SURGERY.

2. On the skin, mucous membranes, or at the junction of skin and mucous surfaces; lip, ala of nose, glans penis, cervix uteri, eyelid. The cylindrical celled epithelioma is more likely to occur in the stomach, the rectum, and uterus.

3. Gastrotomy, gastrostomy, gastrorrhaphy.

The *indications for gastrotomy* are: In the removal of foreign bodies from the stomach, for exploration, for the treatment of various conditions existing in the stomach, pylorus, or lower end of the esophagus (such as ulcer, stricture, etc.).

4. (a) Transverse, oblique, spiral, longitudinal, dentate, T-shaped, V-shaped, and comminuted. (b) By external violence, either direct or indirect; by muscular contraction; spontaneous. (c) Single and multiple; this latter may be double, triple, or quadruple, etc.

5. "Paraplegia below the part injured is present in most cases, and with it some amount of general shock. When the cord is disintegrated or divided, symptoms of spinal myelitis rapidly follow, and a fatal issue often occurs at an early date from toxemia following septic cystitis or sloughing of the nates. The special phenomena of paraplegia in the region referred to are:—complete paralysis of the muscles of both limbs, including those passing to them from the trunk; total anesthesia of the legs, gluteal and perineal regions, and possibly the lower part of the abdomen; whilst, if the vesical centers are destroyed, there is total paralysis of the bladder, with relaxation of the sphincter, dribbling of urine, which early becomes ammoniacal, and cystitis, due to trophic changes; if the centers escape, retention with overflow is the usual result; the rectum and sphincter ani are paralyzed, causing incontinence of feces, the passage of which is unrecognized from the anesthetic condition of the anus."—(Rose and Carless' *Manual of Surgery*.)

6. Sarcomata, chondromata, osteomata, carcinomata, fibromata, myxomata, angiomata, myelomata.

8. *Predisposing causes*: atheroma, syphilis, old age, intemperance, undue exertion, embolism. *Exciting causes:* injury to an artery, increased blood pressure (either from increased heart action or from obstruction beyond the aneurysm), blows, strains, sudden exertion.

9. Litholapaxy, suprapubic lithomy, vaginal lithotomy, lithotrity (and extraction with forceps or by mere manipulation).

11. Laparotomy should be performed at once, the abdominal cavity must be thoroughly cleansed out, and particular attention be paid to asepsis, disinfection, and drainage.

14. Coryza or "snuffles," with a thin, watery discharge which does not readily respond to treatment, and which causes excoriation; fissured lips, "rhagades," and a hoarse cry.

15. The pediculi pubis are the shortest of the pediculi, but are broader and flatter than the pediculi capitis. The head is fiddle-shaped, and they bear a general resemblance to a miniature tortoise or crab. They have six legs; the two front pairs are used for walking, and with the claspers on the hinder legs they stick tight to the pubic hair, and generally have the head buried in the follicular orifice. The nits are situated quite near the base of the hairs.

The *symptoms* are: itching in the pubic and perineal regions, excoriations from scratching, hemorrhagic puncta or papules.

Treatment: The pubic region should be shaved, washed with soap and water twice a day, either mercurial ointment should be rubbed in, or lotion of corrosive sublimate should be applied.

OBSTETRICS.

2. The liquor amnii is the fluid contained in the amniotic sac; it is alkaline in reaction, has a specific gravity of about 1.001 to 1.008, its quantity is variable, but is generally about two pints. It consists chiefly of water, but contains small

amounts of albumin, epithelial cells, urea, phosphates, chlorides, etc. Its source is unsettled.

Functions: (a) *During Pregnancy*: (1) As a protection to the fetus against pressure and shocks from without. (2) As a protection to the uterus from excessive fetal movements. (3) It distends the uterus, and thus allows for the growth and movements of the fetus. (4) It receives the excretions of the fetus. (5) It surrounds the fetus with a medium of equable temperature, and serves to prevent loss of heat. (6) It prevents the formation of adhesions between the fetus and the walls of the amniotic sac. (7) It has been supposed, by some, to afford some slight nutrition to the fetus.

(b) *During Labor*: It acts as a fluid wedge, and dilates the os uteri and the cervix; it also slightly lubricates the parts.

3. Malformations, and displacements of the uterus (chiefly retroversion, and prolapse); inflammations of the uterus or appendages (metritis, endometritis, salpingitis, ovaritis); adherent uterus with perimetritis; undue rigidity of the uterine muscles; extreme laceration, erosion, or ulceration of the cervix; tumors of the uterus; pelvic congestion, acute or chronic.

4. If primary, it is due to slipping of the ligature or injury to the cord; and the cord should be re-ligated in a proper manner. Secondary hemorrhage is due to either: hemorrhagic diathesis, deficient coagulability of the blood, or loosening or tearing of the normal coagulum from the hypogastric arteries. *Treatment*: compression with hare-lip pins, and application around these of a figure-of-eight ligature.

9. The patient (the bowels and bladder having been emptied) should be placed in the knee-chest position, and the uterus replaced by manual pressure. If this proves unsuccessful, a repositor may be used; and the procedure may be facilitated by drawing down the cervix with a volsellum forceps. If the uterus is bound down by adhesions, tampons soaked in ichthyol and glycerin should be placed in the posterior cul-de-sac. After reposition, the uterus should be kept in place by a pessary or tampons.

In case the uterus becomes incarcerated, in addition to the above procedures, anesthesia may be necessary; and if reposition is not possible, the advisability of inducing abortion or of performing a hysterectomy may have to be considered.

13. Fever, chills, pulse weak and rapid, pain in lower abdomen and thighs, anorexia, pelvic tenderness, prostration; there may be painful urination and defecation.

Drainage may take place through the vagina, or through the abdominal wall.

14. Vaginismus is a condition of painful and spasmodic contraction of the vaginal orifice, which renders coitus either painful or altogether impossible. Its *causes* are irritable hymen, ulcer, or fissure anywhere in the immediate vicinity, urethral caruncle, carunculæ myrtiformes, a long perineum with vaginal orifice placed too anteriorly. The *treatment* consists in removing the cause when possible, tonics and general constitutional treatment; dilatation of the vaginal orifice may be necesary; local application of a 5 per cent. solution of cocaine will relieve the hyperesthesia and allow of coitus.

PATHOLOGY.

3. Cloudy swelling, fatty degeneration, coagulation necrosis; these occur principally in the muscles, the liver, kidneys, and the heart.

9. Impaction in the gall duct, causing biliary colic; dilatation and inflammation of the gall-bladder; hypertrophy and cirrhosis of the liver; carcinoma of the gall-bladder.

10. Formation of gummata; meningitis, myelitis, and degenerative changes in the nerve tissues; hemorrhages; encephalitis. As a result there may follow: mania, melancholia, paretic dementia, pseudoparesis, myelitis, paraplegia, hemiplegia, locomotor ataxia, general paresis, neurasthenia, hysteria, epilepsy, and neuralgia.

11. Triceps, anconeus, supinator longus, extensor carpi radialis longior, brachialis anticus, supinator brevis, extensor carpi radialis brevior, extensor carpi ulnaris, extensor communis digitorum, extensor indicis, extensor minimi digiti, extensor pollicis longus, extensor pollicis brevis, abductor pollicis.

12. Ewald's test breakfast consists of one or two dry rolls, or one or two slices of dry bread; and about two-thirds of a pint of water or weak tea. This is taken in the morning, no food having been taken since the previous evening. The contents of the stomach are withdrawn about an hour to an hour and a half after the test meal, and examined.

15. Cancer of the stomach, cancer of the pancreas, aneurysm.

THERAPEUTICS, PRACTICE, AND MATERIA MEDICA.

1. It is used internally in asthma, bronchitis, and constipation; locally for the eruption in poisoning by rhus toxicodendron.

3. It slows the heart, increases the force of the systole, and prolongs the diastole. It also causes a rise in blood pressure. On the kidneys it exerts more or less of a diuretic action.

4. Iodism is the name applied to the condition resulting from the prolonged use of iodin or the iodides.

The symptoms of iodism are: Severe coryza, sore throat, conjunctivitis, headache, nausea, anorexia, metallic taste in the mouth, increased flow of saliva, eruption on the skin which may go on to suppuration.

6. Tinctura strophanthi. Dose ♏viii. It paralyzes the muscles, first causing stiffness, and later, loss of voluntary movement; the heart is particularly influenced. In small doses it has the same effect as digitalis, increasing the force of the systole, prolonging the diastole, stimulating the cardiac contractions, and causing increased blood pressure. It is also a diuretic.

7. It is used as an expectorant in bronchitis, and as a gastric and hepatic stimulant.

9. (1) Confectio sennæ; dose, ʒj. (2) Fluidextractum sennæ; dose, ♏xxx. (3) Infusum sennæ compositum; dose, ʒiv. (4) Syrupus sennæ; dose, ʒj. (5) Pulvis glycyrrhizæ compositus; dose, ʒj.

12. The hydrochloride. As an expectorant, gr. 1/30; as an emetic, gr. 1/10.

13. Benzoic acid.

14. Severe, sudden, abdominal pain; collapse; small, rapid pulse; the abdomen is distended and tender; the legs are drawn up and the thighs flexed; there may be nausea and vomiting; blood examination shows the presence of leucocytosis.

15. (a) Liquor potassii arsentis, ♏iij. (b) Liquor sodii arsenatis, ♏iij.

BULLETIN OF APPROACHING EXAMINATIONS.†

STATE.	NAME AND ADDRESS OF SECRETARY.	PLACE AND DATE OF NEXT EXAMINATION		
Alabama*	W. H Sanders, Montgomery	Montgomery	April	1-6
Arizona*	Ancil Martin, Phoenix	Phoenix	April	1
Arkansas*	F. T. Murphy, Brinkley	Little Rock	April	9
California	Chas. L. Tisdale, Alameda	San Francisco	April	16
Colorado	S. D. Van Meter, 1723 Tremont Street, Denver	Denver	April	2
Connecticut*	Chas. A. Tuttle, New Haven	New Haven	July	9
Delaware	I. H. Wilson, Dover	Dover	June	18
Dis. of Col'bia	W. C. Woodward, Washington	Washington	April	11
Florida*	J. D. Fernandez, Jacksonville	Jacksonville	May	15
Georgia	E. R. Anthony, Griffin	Atlanta	April	—
Idaho	J. L. Conant, Jr., Genesee	Boise	April	2
Illinois	J. A. Egan, Springfield	Chicago	April	17

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious disease reported to the Sanitary Bureau, Health Department, New York City, for the week ending March 9, 1907:

	Cases	Deaths
Tuberculosis Pulmonalis	494	225
Diphtheria	278	29
Measles	416	14
Scarlet Fever	320	12
Smallpox	—	—
Varicella	90	—
Typhoid Fever	44	4
Whooping Cough	59	8
Cerebrospinal Meningitis	24	24
Malarial Fever	...	.. .
Totals	1725	316

Rhinopharyngitis Mutilans (Destructive Ulcerous Rhinopharyngitis): a Problem in Tropical Pathology.—James Farquharson Leys states that it may help the European reader to realize the extensive and striking prevalence of this rhinopharyngitis in the few limited regions from which it is reported, if he will apply the figures representing its prevalence in Guam (one to one and five-tenths per cent.) or in the Dominica district (three per cent.) to some populations with which he is familiar. A single case of this kind in Europe would probably be attributed to tuberculosis or tertiary syphilis. The disease appears to be of an infectious nature. It seems to be local, not constitutional, and this suggests, according to the writer, that its cause may be of a fungoid nature. The destructive and mutilating serpiginous ulceration of the nasopharynx is usually self-limited, and has little or no effect upon the general health. The disease begins in the soft parts, but later attacks the bone of the palate and nasal septum, and finally destroys these entirely. At this stage the disease usually arrests itself, leaving the victim with no septum, the nasal cartilage and skin fallen in, and the nose and mouth one large cavity. The writer believes that this disease is not a late manifestation of yaws or of any other constitutional disease, but that it is more probably a peculiar, independent, local affection caused not improbably by the local invasion of some infecting organism. He declares, however, that he does not wish to advocate any mere hypothesis as to its etiology.—*The Journal of Tropical Medicine.*

Barlow's Disease in the Island of Cuba. Joaquin L. Dueñas says that infantile scurvy exists in the Island of Cuba, under the same forms and identical features assigned to it in other countries. Its frequency is apparently less than in other parts of the world, but the writer believes that it will increase as the disease becomes better known. The disease was developed in children fed upon boiled cow's milk, sterilized cow's milk, condensed milk, and maternal milk; and for some reason the employment of each of these modes of feeding was disadvantageous to the health of the child. As the immense majority of children reared upon the same kind of nourishment do not suffer from scurvy, it would seem that the true cause of the disease must be traced either to the presence of some noxious element contained previously in the milk, or in its subsequent development in the intestine by virtue of a defective elaboration of the ingested material. It must be admitted, too, that some organic or functional deficiency in the individual is a causative factor of great importance. In the writer's opinion the toxic agent which produces the scorbutic anemia of the child and the hemorrhagic syndrome which characterizes it, is of a chemical, and not of an infectious, nature. Barlow's disease differs from rickets. Of the author's seven cases, three offered no signs of rickets, neither did they present osseous symptoms, nor the premonitory signs described by Comby, at the level of the stomach, intestine, liver, spleen, and lymphatic glands. The writer concludes that he can add nothing new to what is already known with regard to the diagnosis, prognosis, and treatment of infantile scurvy.—*Archives of Pediatrics.*

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine-Hospital Service, during the week ended March 8, 1907:

FRACTURE DISLOCATION OF THE SPINE.*

BY SAMUEL LLOYD, M.D.,

NEW YORK.

PROFESSOR OF SURGERY, NEW YORK POST-GRADUATE MEDICAL SCHOOL; ATTENDING SURGEON, NEW YORK POST-GRADUATE HOSPITAL AND BABIES' WARDS; ATTENDING SURGEON ST. FRANCIS HOSPITAL

ACCORDING to the statement made by Keen,[1] 60 per cent. of the fractures of the spine are fracture dislocations, while 20 per cent. are simple fractures, and the remaining 20 per cent. simple dislocations. Kocher[2] has classified the injuries of the vertebral column, and Von Bergmann presents this classification with a few practical modifications as follows:

Partial injuries: (1) Distortion; (2) single dislocation of the lateral joints; (3) contusion; (4) isolated fractures of the vertebral column (pressure fractures); (5) isolated fractures of the arches and spinous processes. Complete dislocations with fracture: (6) Complete dislocation (dislocation of the lateral joint and displacement in the region of the intervertebral disk); (7) dislocations with fractures due to pressure dislocation of one or both lateral joints and pressure fracture of the body; (8) complete dislocation with fracture, dislocations with diagonal fractures, dislocation of the lateral joints, and dislocation in the region of the vertebræ.

Distortion may be produced by a fall on the head with a bending forward or backward of the body. Kocher says: "As long as the continuity of the bodies of the vertebræ and their ligaments is preserved, overextension may simply produce distortion. If extension is associated with torsion, the joint is more affected on the side to which the face is turned. With flexion and rotation, on the other hand, the opposite joint suffers most damage. Sometimes several vertebræ are affected at the same time. The fourth, fifth, and sixth cervical vertebræ are most commonly affected."

The symptoms of this condition are those resulting from pain. The head is held stiff, the ear drawn down toward the shoulder of the affected side, and the face turned toward the healthy side. All motion is avoided, and pressure—whether upon the head or the lateral joints or spinous processes, or upon the neighboring vertebræ—causes pain. Occasionally there are symptoms of injury to the cord present in these cases. This is usually due to hematomyelia (Wagner-Stolper[18]). The cord is rarely if ever crushed. Fixation and extension constitute the best treatment. Recovery occurs usually in from three to four weeks, although the patient should be kept under observation for a longer period of time.

"There may be isolated bilateral dislocation." The rare cases of bilateral dislocation, without injury to the cord, are considered as isolated dislocations. In an isolated dislocation the intervertebral disk remains intact. A blow upon the nape of the neck, or a fall backward on the head, will sometimes produce a unilateral dislocation of the lateral joints. The *x*-rays usually will show the displacement of the bone, and the position of the head—drawn down toward the healthy side—will usually enable one to make the diagnosis. The cord is not apt to be affected, although hematomyelia may be present. In these cases reduction should be effected under an anesthetic, and then fixation and extension should be continued. Isolated fractures of the bodies of the vertebræ are always pressure fractures, and are usually caused by a fall upon the head or neck, or upon the sacrum or feet. They are most common in the dorsal and upper lumbar regions, but rare in the cervical. In these cases a certain amount of anteroposterior deformity is noticeable, although this may be so slight as to be overlooked. The deformity may disappear, too, as soon as the patient is in a recumbent position, but may become patent when the erect position is assumed. The symptoms may be so slight as to be completely overlooked.

Fractures of the sternum should lead one to suspect an injury to the vertebral column. Sometimes the cord is completely destroyed, at other times it is simply pressed upon by the displaced vertebral bodies.

Chipault[3] has suggested wiring the spinous processes in these cases in order to prevent slipping, but often they can be treated by a plaster jacket with extension and counterextension, and should remain in a recumbent position. In case the cord has not been injured this would be the better method of treatment, but with the appearance of pressure upon the cord at any time, operation should be undertaken. This pressure may be due to hematorachis, hematomyelia, or—when it comes on later—to the formation of callus, decreasing the size of the spinal canal and making pressure upon the cord.

The fractures involving the posterior portion of the spine, spinous processes, and arches may frequently be treated simply by rest. When, however, a fracture of the spine or laminæ, or both, is accompanied by symptoms referable to the cord, operation should be undertaken at once, for the probabilities in these cases are that the arch has been driven in and is compressing the cord, or spicula of bone have penetrated it. One must also remember, in this condition, as in the former, that a gradually increasing paralysis, coming on at any time after the injury, is indicative of pressure upon the cord, and should call for immediate operative interference.

The fracture dislocations, on the other hand, present a much more difficult problem. Most authors agree with the statement that they are produced by a bending of the body either forward or backward, causing a crush and dislocation of the body or bodies of the vertebræ, and usually accompanied by very marked destruction of the spinal cord itself. Occasionally these conditions are produced by very powerful muscular action, according to Cheyne.[4] Usually they are caused by indirect violence, as when

*Read before the Medical Society of the County of New York, February 25, 1907.

the body is bent forcibly downward by the caving in of an embankment or the falling of some heavy weight. In these cases the spine, after it has been bent over, jumps back again, so that little or no deformity may be noticeable at the time of injury. Thorburn[5] believes this to be a frequent cause of the condition, and in the cervical region considers that they are twice as common as those in which the displacement is permanent.

Chipault, on the other hand, after a consideration of a very considerable number of cases, does not believe that this temporary displacement occurs. The majority of observers, however, have considered that this was the usual cause of the condition, and it seems to explain much better the extensive lacerations of the cord which are usually found in this class of cases.

In my paper, reviewing 103 cases of spinal surgery, published in 1891,[6] I quoted Hutchinson's[7] conclusions based upon twenty post-mortem examinations. He says: "Permanent compression of the cord or of any part of it is very rare—not more than one in ten—and as most fractures in this region are due to bends, fractures of the laminæ are of little consequence and never cause compression. Instances of great displacement sometimes occur, and can rarely be benefited by operation, while cases in which during life there is the greatest displacement are not always the most serious." In considering this question, I found that in 35 cases in which the cause of compression was given, 11 were due to temporary, and 13 to continued bony displacement, thus controverting the statement made by Hutchinson, and showing that continued depression of the bone was the most frequent cause of the compression of the cord.

The cases in which the cord is found crushed, but not compressed (at operation or post mortem), are probably explained by the springing back of the spinal column into position when the patient is straightened up and laid in a horizontal position. They may spring back so nearly into normal position that it is almost impossible to recognize any deformity. Sutton[8] has reported an interesting case of intrauterine fracture of the spine caused by a fall of the mother at the fifth month of gestation. This child was born at the eighth month, and, while the upper part of the body was fully developed, all below the umbilicus corresponded to the development of a five-month fetus.

These cases of fracture dislocation of the spine resolve themselves, therefore, into two classes: (1) those in which the spinal cord is not injured, and (2) those in which there is more or less interference with the functions of the cord itself. In the first set of cases operative treatment would not be indicated in the beginning. The only symptoms directly due to the fracture are, first, those common to all other fractures, such as deformity, increased mobility, crepitus, etc. The patient, however, in a case of fracture of the spine, is unable to walk, is markedly shocked, and even though the examiner does not succeed in eliciting crepitus or false point of motion, which would probably be very dangerous symptoms to look for in these cases, he will readily make out a point of marked tenderness along the spine. Local signs are usually unsatisfactory. Either no irregularity can be detected, or an irregularity that is so slight as to be of little consequence—sometimes a prominence of the vertebra may be noticeable, or there may be a depression along the line of the spinous processes, or we may be able to make out a lateral displacement. When these signs are present, they are a great aid in diagnosis, and would be almost conclusive evidence of the location of a fracture if associated with marked tenderness on pressure, localized pain—increased materially whenever the position of the patient is altered—or with a fracture of the sternum. Extravasation of blood, too, may occur early, and by the time the patient is examined it may be possible to recognize a distinct infiltration of the surrounding tissues.

In making the examination, the greatest care is essential, for the slightest twisting of the patient may displace the injured vertebræ and cause compression or laceration, or even complete destruction of the cord. Lathrop[9] says that with the aid of the Roentgen ray the fracture can be definitely seen and splinters of bone can be located; but it is impossible in many of these cases, in my opinion, to get a satisfactory *x*-ray plate, nor is it advisable to manipulate the patient any more than is absolutely essential to remove him from the place of the accident and to institute the proper treatment.

I do not myself favor the application of plaster-of-Paris unless there is marked mobility of the fragments, but think that the patient is better if placed in a horizontal position on his back, on a springless bed, and with sufficient extension and counterextension to compel him to remain in the dorsal position. In those cases in which there is marked mobility of the fragments, and where it is difficult to restrain the patient and keep him quiet, a plaster jacket should be applied.

A much more complicated picture is presented when the spinal cord is involved. If it were not for some of the recent articles that have been published, referring to the possible regeneration of the spinal cord, I should feel that the last word had been said on that subject in the articles I read before the American Medical Association, Section on Surgery, in June, 1900,[10] and before the Surgical Section of the Rochester Academy of Medicine, May, 1901.[11] The question, then, is the one asked by Burrell:[12] "Is the spinal cord irremediably damaged, and can we tell whether a spinal cord is irremediably damaged, or not?" To this must be added another: Does regeneration of the spinal cord take place, and, if so, what must be done in order to put it in the proper position for regeneration?

The symptoms in these cases are those due to the compression or destruction of the cord itself, and we owe to Thorburn much of the accuracy of our knowledge of the symptomatology of this class of injuries. At the time that he published his brochure (1889)[13] he said that surgeons would probably in the near future open the spinal canal with as little danger and as little hesitation as they now operate upon the cavity of the cranium. This prophecy has been abundantly fulfilled.

Burrell[12] recognizes three types of cases: (1) those in which the cord is crushed; (2) those in which doubt exists as to whether the cord is irremediably damaged, and (3) those in which it is fair to assume that the cord is not irremediably damaged. The first forms by far the largest class of spinal injuries. There is one other condition that has been found in a certain number of these cases, and that is compression by blood-clot. Four of these cases were reported in my first paper, and Keen's case of spinal hemorrhage is reported in full in my paper read before the Rochester Academy. At this time I also reported a case of my own of the same character.

Walton[14] asks whether we really have reliable symptoms establishing, except through their persistence, irremediable crush of the cord, for, if we have not, are we doing justice to the patient when we rely on the time-honored dictum that the damage was

done at the moment of impact, that the pressure of fragments has been spontaneously relieved, and that nothing can be accomplished by operation He says that fracture of the spine with complete transverse lesion of the cord is accompanied by immediate relaxed motor paralysis involving the parts below the level of the lesion. There is entire absence of rigidity, of spasm, convulsive movement, or other irritative sign in the motor sphere. The statement that signs of motor irritation may appear at the level of the lesion seems based rather upon theoretical considerations than upon actual observation. Partial injury to the cord, including the results of hemorrhage, may be indicated by a slower onset of paralysis, by unilateral or irregular distribution (affecting for example, the arms more than the legs), by the preservation, or comparative preservation of reflexes, and by the rapid improvement. In diagnosticating the level of the lesion by studying the muscles involved in the paralysis, the tables of Thorburn, based on clinical rather than on anatomical or experimental observations, have stood the test of practical application. It would appear that the motor symptoms may reach a much higher level than the sensory—at least in case of lesion of the lumbar enlargement.

In fracture with total transverse lesion the area of anesthesia is generally sharply marked, and at a level corresponding to the segment crushed—that is, at a level materially below the seat of the lesion. Most authorities agree that the upper roots of the brachial plexus supply the cap of the shoulder and the radial side of the arm and hand, while the lower roots supply a strip down the ulnar side of the arm and hand. The seventh dorsal segment supplies the ensiform region; the eleventh dorsal, the umbilicus, and the lumbar, the front and outer and inner aspects of the thigh to the groin, and the inner aspect of the leg. The sacral supplies the region below the knee in front on the outer aspect, as well as the whole or greater part of the foot. It supplies also the back of the leg and a strip in the middle of the posterior surface of the thigh, and the saddle-shaped area, the perineum, scrotum, and penis. The fourth cervical segment furnishes sensation down to a line below the clavicle adjoining the distribution of the second dorsal. The absence of representation on the trunk of the intervening segments is explained by the fact that in the budding and growth of the upper extremity, the areas supplied by the fifth, sixth, seventh, and eighth cervical, and the first dorsal are carried down the arm. For a similar reason the twelfth dorsal closely approximates the third sacral on the buttocks. It is probable that complete anesthesia in any area implies loss of the segments above and below the one which supplies that area, as each part of the body receives sensory fibers from these segments (Sherrington). It should not be forgotten that in case the roots are crushed at the same level as the cord the anesthesia will reach to the level of the lesion. Below the well-known strip of hyperesthesia which surmounts the anesthesia and points to root irritation, is apt to appear a strip of thermal anesthesia and of analgesia (Kocher).

Incomplete anesthesia points to incomplete lesion of the cord. The same is generally, but not invariably, true of anesthesia of limited or of unilateral distribution. It is generally true of anesthesia limited to regions far below the level of the lesion, and in general the varying modification of the different forms of anesthesia at different levels points to incomplete lesion. Injury to nerve roots alone sometimes appears in the cervical region after stretching and bruising—perhaps with temporary displacement of vertebræ and rupture of ligaments (distortion). In this lesion the sensory symptoms, like the motor, are apt to be limited to the arms.

Retention, rather than incontinence of urine, is the rule in all varieties of spinal fracture with injury to the cord, even when the lesion involves the lumbar region. There may be either retention or incontinence of feces, more often the former. The sensation in the rectum and bladder may be preserved in incomplete lesions, even though voluntary evacuation is impossible. The symptoms referable to vasomotor disturbance are variable and baffling. The most common observation is a rise in the superficial temperature of the lower extremities, which may be replaced later by coolness of the extremities, and sometimes—though not usually—by marked coldness. The skin is generally dry. Sweating is absent.

The knee jerk is lost in case of complete destruction of the cord. The superficial reflexes are also generally lost or diminished in these cases—probably always lost in complete lesions. This may not necessarily be limited to the reflexes below the lesion, but may involve those higher up. The Babinski reflex may appear when no other reflex is present.

With these data at hand we can form some fairly definite conclusions with regard to the condition of the cord—whether there is a complete or an incomplete destruction. In one of my other papers I said that in the former case it is useless to operate; in the latter it becomes necessary to consider at what time the operation can best be performed.

If operation is undertaken at once there is danger of interference where a spontaneous cure would result if the patient were left alone, or where a complete destruction of the cord renders operative interference useless. If, however, operation be delayed too long, and a compression be allowed to continue, a degeneration may result which would be as serious as though the functions of the cord had been destroyed by the original injury. Horsley insisted that operation should be undertaken early, and this was my own opinion as expressed at that time, provided the symptoms present indicated interference with the functions of the cord. In other cases I should wait until the shock following the injury had been overcome, watching the patient's condition carefully, however, and at the slightest indication of any symptoms pointing to an extension of the interference with the action of the spinal cord, whether that interference be due to hemorrhage or to compression from depression, callus, or to the exudation of lymph, I should operate at once.

In this connection, however, it is important to take into account the general results following fractures of the spine treated without operation, and the same statistics that I used in my former paper will illustrate this point. Thus, Gurlt reported 217 deaths out of 270 fractures, or over 80 per cent.; while Burrell, from the tables of the Boston City Hospital, cited 82 cases with 64 deaths, or 70 per cent., and of the 22 per cent. of recoveries only 11 per cent. were satisfactory, the other 11 per cent. being completely disabled. Burrell has published a series of 244 cases in his paper already quoted, but as he does not say whether this last series includes both operative and nonoperative cases, we have thought best not to include it here. These statistics also show that in the fatal cases the greater number of deaths occurred within a few days. It is, therefore, evident that if we operate immediately after the injury we will have failures that should not be charged against

the operation itself, and if possible we should wait before operating until the question can be settled whether the patient will overcome the shock or succumb directly to the effects of the injury.

There is another objection to immediate operation. In so-called concussion of the spine there may be a certain amount of anesthesia and paralysis. The recovery, however, will be complete, or at least so nearly so that no appreciable lesion can be made out. Immediate operations in these cases would be unnecessary, as they would have recovered spontaneously had they been left alone for a sufficient length of time. It is impossible, too, in the first few hours to determine with any degree of certainty how severe the injury really is, nor can we absolutely localize the injury to the cord. In my opinion, therefore, we should wait until this period of shock has passed and until it is evident that there will be no spontaneous recovery complete enough to render life bearable. If after this period has passed the patient still continues to improve, no operative interference should be considered, but as soon as the symptoms begin to show retrograde phenomena, or seem to have reached the end of the improvement, operation should be undertaken.

In those cases where no improvement follows the recovery from the shock, and yet the suspicion remains that a complete crush of the cord has not occurred, we should operate immediately. This divides the cases, therefore, as follows: (1) those that evidently have complete destruction of the cord; (2) those where, following the recovery from the shock, it is evident that the lesion of the cord has not been completely destructive and yet no improvement is noted. Operation here should be done as soon as these facts are determined; (3) those where the lesion of the cord is incomplete and where the symptoms of compression are extending as evidenced by increasing paralysis and the enlarged area of anesthesia; here operation should be undertaken immediately, as there is a hemorrhage, an inflammatory thickening, or some acute process present that threatens the destruction of the cord unless it is controlled; (4) those in which improvement is noted at first but is arrested later; operation in these should be done as soon as it is settled that the improvement has ceased; (5) those who made a full recovery, or almost so, under the usual conservative methods, where the paraplegia or other symptoms develop at a later date; this is probably due to compression from callus, and the operation should not be delayed any longer than is essential to establish the fact that there has been a loss of function.

Regional statistics are important in determining the result of operations. Thus we find out of 27 affected in the cervical region, operated on immediately, 21 died, while out of 10 operated on at a later period only 2 died; in the dorsal region, out of 49 operated on immediately, 23 died, while of those who were operated on later, only 5 died, from a total of 63. Even in the lumbar region the same disproportion exists; thus, from 6 immediate operations, 4 died, while from 22 done at a later period, only 4 were fatal.

The following table shows the results better than any description I can write:

Cervical Region.	Immediate Operation.	Later Operation.
Deaths	21	2
Recovery	0	2
Improved	2	1
Not improved	0	4
Subsequent death	4	3
	27	12

Dorsal Region.	Immediate Operation.	Later Operation.
Deaths	23	5
Recovery	4	10
Improved	9	18
Not improved	6	16
Subsequent death	7	16
	49	65

Lumbar Region.	Immediate Operation.	Later Operation.
Deaths	4	4
Recovery	1	6
Improvement	1	6
No improvement	0	4
Subsequent death	0	2
	6	22

Sacral Region.	Immediate Operation.	Later Operation.
Deaths	0	0
Recovery	0	1
Improved	0	3
Not improved	0	0
Subsequent death	0	0
	0	4

This emphasizes the fact, which is already recognized, that the cervical is the most dangerous region for operation, and at the same time the least satisfactory in its ultimate result. The results in the dorsal region have improved since the earlier statistics, due probably to the improvement in technique, the greater rapidity with which the operation is done, and the fact that operations are done earlier than was formerly the case. The lumbar region shows a surprisingly small number of surgical interventions when it is taken into account that the safety of the operation in this region and the decided improvement following it was emphasized in all the earlier papers on this subject. I cannot but feel that some of the incomplete recoveries recorded have been due to incomplete relief of the compression. Unless the operator has had considerable experience in spinal surgery, it is a very easy matter to overlook a compressing point. It is essential, in order to make the operation perfectly successful (1) to remove enough laminæ to absolutely settle the fact that there is no remaining compression of the cord; (2) to chisel off any projecting bone, whether it be a portion of a vertebral body or bodies, or one or more articular processes; (3) to remove all blood clots, even though laminæ of unaffected vertebræ have to be removed to get beyond the hemorrhagic area; (4) to look out for thickening and compression resulting from inflammatory processes or injuries of the structures within the vertebral canal. It is sometimes difficult to be absolutely certain whether all compression has been done away with, but one usually recognizes the fact that the cord is smaller in the exposed area than it should be, and that its pulsation is not complete, not as full as in a normal cord. Care should be taken, therefore, that the cord dilates to its full extent, and that the pulsation returns. This can happen only where the cord has not been completely destroyed. And if the operator cannot be sure of this fact without opening the dura, he had better make an incision and definitely determine whether the integrity of the cord has been preserved. He will also sometimes recognize the fact that the dura is discolored, looks as though there has been an intradural hemorrhage, and while this accident, if it has occurred, has probably produced more or less disintegration of the cord itself, the dura should be opened and this blood clot removed, for one may look for a certain amount of regeneration in the cord provided it is relieved from the compression at a sufficiently early period, and provided it has not been completely destroyed.

After commenting on the former statistics of the operation, Keen said: "With such statistics before us it is impossible to draw any other conclusion than that operation is advisable in case extension directly after the accident fails to reduce the deformity. Of course, the limitations arising from the time that has elapsed since the accident, the region involved, and the severity of the lesion must be given due weight in reaching a conclusion in any given case. In an instance, therefore, of such gravity, followed by such an immense percentage of deaths, if no operation be done, it would seem to be advisable, with our present experience, in all suitable cases, to give the patients the real, though often desperate chance that operation offers, and that the operation should be done at a much earlier period than has hitherto been the rule." If this was the conclusion reached after a careful weighing of all the data presented up to that time, how much more emphatically may we advise operation at the present time.

This brings us, then, to a consideration of the question of regeneration of the cord after complete injury. In view of what has been said by several recent writers on the subject, and also of the experimental work that has been done along this line, is it possible that in our former papers we were mistaken in saying that complete destructive lesions of the cord could not be improved by operative measures, and therefore should not be operated upon? Bolton[15] says: "Many observers have studied the processes of repair of injuries of the cord in many classes of vertebrates, and while there is complete regeneration after division in some of the lower orders, in mammals there is practically none. In the immediate neighborhood of the lesion degenerative changes occur in the ganglion cells and fibers cut off from their trophic centers; while in those in which the connection is preserved there is a feeble and never-completed attempt at regeneration only. The lesion is repaired by the growth of ordinary cicatricial tissue from the connective tissue cells of the blood-vessels and the Pia mater."

In 1892 Leckie[16] suggested the feasibility of removing a sufficient amount of the spinal column, in cases of destruction of a small portion of the cord after fracture, to permit of the approximation of the separated ends by stitches. Chipault and Maydl had both discussed this question of suture of the spinal cord, and dismissed it as impossible owing to the inelasticity of the cord itself and the resistance of the ligaments. Leckie proposed to shorten the spinal column in order to overcome these difficulties, and to permit of the divided ends of the cord being placed in apposition and the suturing of the membranes. There should be no insuperable difficulty, he says, in the removal of a part or the whole of a vertebra, or even portions of two adjacent vertebræ.

Mixter and Chase[17] report a very suggestive case, which is summed up as follows: "High fracture of the spine—sixth cervical vertebra—in which all the classical symptoms were present, upon which authorities have previously based their opinion that operation was contraindicated, because it suggested total transverse lesion with a crush of the cord beyond repair. The patient was operated upon within twenty-four hours, and lived eleven and a half months, during which time there was marked and steady improvement. From a condition of total paralysis involving all of the body excepting the anterior surfaces of the arms and the right hand, and the shoulders and scapular regions and head, the patient regained nearly normal use of his hands and arms, and such improvement in the condition of his body and legs as to lead one to believe that if an unfortunate complication had not arisen further improvement might have been expected. From a condition of total anesthesia over the area above referred to there was practically complete recovery by the ordinary tests. A series of cross sections of the spinal cord from the pons to the coccyx made it possible to study the paths of degeneration following a crush at an unusual length of time after injury. Pathological anatomy of the spinal cord showed that descending degeneration of all injured axons occurs in motor tracts below the level of the lesion, and of the common tract, which is composed of short, descending sensory collaterals from injured sensory neurons. It shows the occurrence of ascending degeneration of all sensory axons involved in the lesion. The sections demonstrate that normal sensory and motor axons exist at the seat of the lesion, though their functions were interrupted at the time of the injury, which suggested total destruction of the cord. The operation showed fracture and depression of the spinous processes and laminæ apparently lying against the cord with a blood clot under the laminæ, but none under the dura. The condition of the bodies of the vertebræ not known." It should be noted that no sign of regeneration was found.

The question is pertinent—What is the value of operation in injuries to the spinal cord? (1) It removes depressed fragments of bone apparently lying against the cord. (2) It removes blood clots. (3) It allows the escape of exudate and makes room for inflammatory thickening. (4) If extensive hemorrhage is present, either extra- or intradural, it relieves pressure from the cord. It has been shown that degeneration from pressure appears within four days. If a cord is injured by crush and not totally destroyed, the continued pressure of a blood clot may succeed in completing total destruction. (5) Traumatic spinal edema may be of such extent as to demand greater space for enlargement of the cord to avoid further destruction of fibers. (6) There is absolutely no method by which one can early diagnosticate slight or great pressure of a fragment of bone, the pressure of a small or a large hematoma, whether there is a momentary pinch of the cord or slight pressure. (7) The fact that the cord looked normal in these cases does not preclude the possibility that pressure had existed, nor prove that a condition had existed in which drainage and relief of pressure were not distinctly beneficial. (8) The patients did not suffer from any ill effect of the operation *per se*. The dangers of operation are very slight compared to the possible benefit, and the further satisfaction is obtained that the surgeon *knows* that continued pressure does not exist. Typical symptoms of a complete transverse lesion are not infallible, in which case the surgeon is not doing all in his power to relieve the patient's condition unless he operates.

As a rule, operation in most if not all of the cases can be delayed a few hours until a greater stability of the nervous system is regained; a few cases might impress one with the immediate necessity of operation. It seems reasonable, then, to assume that even with the appearance of total destruction we have to do with a condition which for a time has interrupted the registration of sensation and motion on the cerebrum over certain neurons which after regaining equilibrium will resume their functions. Though fiber degeneration persisted through the year following the operation, and no signs of regeneration were made out in the microscopical examination, the suggestion seems pertinent that the steady improvement

indicated an increased transmission of impulses through the remaining scattered fibers, the analogue of which is found in the increase of functions occurring in the kidney after unilateral nephrectomy, showing the power of nature to accommodate herself to adverse conditions.

Thomas[19] has examined the cord microscopically in several cases dying within a few days of the accident, and he emphasizes the fact that hemorrhagic conditions exist as well as marked degenerative changes of the cord itself, for a considerable distance beyond the actual crush. He calls attention to the fact that sensory and paralytic symptoms are of the greatest value for the diagnosis and the location of the injury to the cord, but that the injury is apt to be even higher than the symptoms would indicate. This bears out a suggestion that I made in a former paper with regard to the necessity for the surgeon to carry his exploration farther than the involved segment, and it also suggests the possibility of a marked improvement in the symptoms, with an absorption of these minute hemorrhagic areas, as I suggested in a discussion before the New York Academy of Medicine last year.

Weissman's dictum that nerve cells once destroyed are never replaced seems to be true, although some observations, notably those of Worcester and the reports of several operators on the spine, would seem to prove the contrary. Barker[20] says: "Regeneration of severed nerve fibers within the spinal cord and brain is unfortunately very much less complete than in the peripheral regions." Oliver[21] says that "sufficient regeneration of nervous tissue to carry on the functions of the spinal cord does not occur, and no method is at present known by which these functions may be restored.

Dr. L. Pierce Clark[22] concludes that animal experiments fail to provide conclusive data that central tracts of the nervous system ever regenerate so that the former function is restored. In warm-blooded animals, and in the human species in particular, an abortive attempt on the part of the cord to regenerate, is largely, if not solely confined to fibers of undoubted peripheral type. Histological analysis of cases of hemisection, compression paraplegia, myelitis, and other like destructive lesions of the cord, fail to show positive evidence that actual structural regeneration of axis cylinders ever occurs in the central nerve tracts of the human spinal cord. In case of complete division of the brain and spinal tracts, there is simply degeneration followed by sclerosis. A most acceptable reason for nonregeneration of such tracts was shown in the fact that the component nerve fibers did not possess a neurilemma sheath from which nerve regeneration mainly if not solely occurs. This lack in cord and brain tracts in contrast to the regenerating peripheral nerves was due possibly to a difference of embryological origin for the two structures of the nervous system. The seven cases cited by Stewart and Hart of cord regeneration being merely hemisections, either do not fulfill the conditions of test, or lack definite and convincing evidence of regeneration. In cases of complete transverse division of the cord, from either experimental or clinical data, there is not sufficient justification to warrant suture of the spinal cord in an attempt to cure the defect.

None of the cases that have been reported up to the present time as cases of regeneration of the spinal cord have demonstrated to my mind the slightest sign of actual regeneration. Although all of them are reported as complete transverse lesions of the cord, in none of them has that been proven, and it is more than likely that there have been nerve fibers that were not destroyed and that have recovered their function, allowing for a more or less considerable improvement in the patient's condition. My own experience in this condition relates simply to two cases. In both of them there was apparently a complete transverse section of the cord, and in both the whole of the pulpy mass was removed, and a suture applied bringing the severed ends of the cord in apposition. One patient lived but three weeks and showed no signs of regeneration. The other lived for ten months, died of the usual kidney complications, and showed absolutely no recovery of function below the removed segment. Up to the present time it seems to me that we are obliged to confess that spinal regeneration in the human species has not been proven, and that it is fallacious to hold out this hope to the patient. But from a consideration of the cases that we have studied we must agree that our previous statement in regard to complete transverse lesions of the cord is probably too drastic, and that some of these cases would probably be improved if they were operated upon. We should therefore suggest that in the future, and until we have a sufficient number from which to draw conclusions, all of these cases should be submitted to the surgeon for operation. At the same time, as it will not increase the dangers to the patient's life, we should advocate that the plan of approximating the cord, as suggested by Haynes,[23] should be carried out, but would warn operators against making a complete section of the apparently destroyed areas, for fear of cutting out nerve fibers that are not involved in the destructive process and that may resume their normal functions. A long series of histological examinations of these cords will have to be made before the question of regeneration can be definitely settled.

I have now performed laminectomy thirty-two times, and while some of my cases have improved to a marked degree, a very considerable number have shown absolutely no benefit from the operation. In none can I attribute the improvement to regeneration, but rather to the conditions already suggested. If regeneration of the cord does occur, we should have had more improvement in some of the cases that were not benefited.

PATHOLOGICAL CHANGES IN FRACTURE-DISLOCATIONS OF THE SPINE.*

By PEARCE BAILEY, M.D.,

NEW YORK.

The pathology of the bone conditions in fracture-dislocation of the spine is essentially surgical, and my remarks on it must be brief, if, in the limited time, sufficient space is to be devoted to the lesions in the nervous system.

Permit me, then, to dismiss the bone lesions with saying that in one-third of the lesions of the spinal column the cord escapes all injury. This is especially apt to be the case in the cervical region, where the canal is larger and there is greater freedom of movement in the bones. It is also more apt to be the case in children than in adults.

Of the regions affected by fracture-dislocations, the cervical region and lumbar region contain about one-half the cases; the dorsal region the other half. Most of the dorsal fracture-dislocations involve the eleventh or twelfth dorsal vertebra. These produce the lumbar type of paralysis, and so should by right be classed with the lumbar fractures.

Thus, neurologically considered, the great majority of the cases of traumatic spinal paralysis are either of the cervical type (including the first dorsal segment of the cord) or of the lumbo-sacral type, including, of course, the cauda equina. Surgical statistics show a great preponderance of the latter over the former. Possibly some clinical cases, in which the bone lesions are not recognizable and the cord symptoms are slight and inconspicuous, escape identification in surgical wards. If they do, the actual number of cervical and lumbar cases would tend to be more equal.

Isolated fractures of the spinous and transverse processes of the laminæ occur chiefly in the cervical region. Fracture of the spinous process occurs in about 8 per cent. of the cases, and in about 4 per cent. as an isolated condition. Only in the rarest cases does it constitute a menace to life, and then by being thrust forward by muscular violence to compress the cord.

Fractures of the laminæ as isolated conditions also occur in the cervical region. These are sometimes recognizable by digital examination.

Late results of injuries to the bones consist in osteomyelitis, which is very rare, in tuberculosis, and in traumatic spondylitis or Kümmell's disease, which affects most frequently the third and seventh dorsal vertebræ.

While the injuries to the bones are, of course, of great surgical interest, the whole importance of this subject centers about the injury which they produce in the cord, and all clinical expressions should be in terms of cord rather than bone. As far as the membranes of the cord are concerned, they are practically never injured alone. They may be lacerated, and the lacerations cause extensive bleeding within the spinal canal, either inside or outside the dura. In my opinion, however, this never occurs as an isolated condition; that is, it never occurs without there being an extensive contusion of the cord associated with the bleeding. This condition, known under the term of hæmatorrhachis, has played quite an important rôle in the clinical history of spinal cord injuries. A special symptomatology has been constructed for it—notably, shooting pains. The surgeon is on the alert for it, with the idea of relieving pressure and, as a consequence, of relieving symptoms.

*Read at a meeting of the Medical Society of the County of New York, February 25, 1907.

But if, as autopsy records seem to show, and as a careful examination of the literature seems to show, hæmatorrhachis never occurs by itself, but only as a part and parcel of a general spinal-cord injury, there is very little use of operating for it, as the hemorrhage will be rapidly absorbed. I have been on the lookout for this condition for a great many years, and have never yet seen a case of pure hæmatorrhachis.

The cord itself may be contused, lacerated, or cut in two. Its external appearance may show the effect of this by dents, punctate hemorrhages, or dislocations; or else the cord, even when severely injured internally, may show nothing abnormal on its external appearance, the extent of the damage becoming apparent only when it is sectioned. Thus it cannot be said that a cord is normal because at operation its external appearances are normal.

When the cases have not been quickly fatal, and come to operation or autopsy a long time after the injury, the cord is bound down by adhesions to the dura, and the dura by adhesions to the bony canal. The cord is shriveled, oftentimes to one-third of its original size. When removed from the canal and sectioned, it shows to the naked eye a disarrangement of the constituent parts, of which dislocation of the gray matter, fissures, discolorations, and hemorrhages are the common pictures.

In recent cases the cord may be so soft that it oozes out when cut into.

Microscopical examination shows the picture which is described as traumatic degeneration, viz., disintegration of spinal-cord elements, large round cells, myelin drops, blood cells and blood pigment, nerve cells and nerve fibers in various stages of degeneration; in old cases the whole is obscured by an overgrowth of new connective tissue. Properly stained, there will also be foci of ascending and descending degeneration; with a Marchi stain this can be demonstrated five days after the injury.

The hemorrhage in spinal-cord injuries has a predilection for the gray matter. It often occurs as a focus of bleeding at a single point, from which focus columns of blood ascend and descend the cord, in the gray matter. As the blood is absorbed cavities are left in the cord, a condition to which Van Guison gave the name of hæmatomyelopore. This focal hæmomyelia may occur in any region of the cord as part of the lesions secondary to fracture-dislocation. It may also occur as a primary condition, without demonstrable injury to the bone. It is then found only in the cervical region, and results from stretching of the cord in sudden flexions of the neck, *e.g.* diving in shallow water. This condition, which I have called primary focal hæmatomyelia, has a rather unique clinical symptomatology and course, and its prognosis is relatively good.

Finally, small blood extravasations may occur up and down the cord with or without spinal fracture.

The extent of a traumatic lesion in the spinal cord varies from the case where the cord is only lightly contused or pressed upon, causing a few elective, slight, and temporary symptoms, to where it is reduced to a pulp, or even cut in two.

Partial lesions are particularly frequent in injuries to the cervical region and to the lower segments of the cord.

In fractures in the dorsal region the bone displacement is usually extreme and the cord lesion consequently severe. Few dorsal lesions of the cord, therefore, are partial. As a result, the outlook in dorsal cases, as a class, is less favorable than in cervical cases, as a class, in spite of the fact that a

severe cervical lesion is more quickly fatal than a severe dorsal lesion.

By a partial lesion is understood a lesion in which one or more of the spinal functions, *e.g.* paralysis, sensibility, sphincter control, is not included in the paralysis.

Many cases have the appearance, from the presence of all symptoms in pronounced degree, immediately after the accident, of being total transverse lesions; yet such cases in the course of weeks or months may show, by recovery, that the cord could not have been injured even in one-half its extent.

For many years clinicians have endeavored to determine from the clinical symptoms the extent of the damage done to the cord itself, and it has generally been accepted as a guiding rule for operation that total abolition of the reflexes, especially in the cervical region, indicated a total lesion.

This rule is not reliable, as, for several days after the accident, the knee jerks may be absent, then return and become exaggerated; or, in some cervical cases, knee jerks, once exaggerated, may later disappear altogether.

Regarding the question of repair after spinal cord injuries, there are much confusion and haziness of ideas—and also intelligent disagreement on well-defined issues.

The question of repair and recovery after fracture-dislocation presents itself to my mind as follows:

The injury to the cord takes place at the time of the trauma. The cord is bruised or lacerated, or compressed, as the case may be. As a result, there ensue more or less softening and shrinking of the cord. The true damage, therefore, is a result of the initial and brief violence—the secondary and long-continued pressure which may result from a narrowing of the canal having little or no effect. It is as though a banana were in a tube and the tube were suddenly narrowed to half its size—all the injury to the banana would have occurred at the time of compression. So with the spinal cord. It is neither firm enough nor elastic enough, nor tough enough to offer any substantial resistance to compression.

Furthermore, long-continued pressure of the spinal cord seems improbable for the reason that from the moment of the initial compression onward the cord undergoes softening, with a constant reduction in its volume, thus making more room in the canal and less opportunity for the so-called permanent compression. This explanation leaves out of account two conditions—one in which splinters of bone have pierced the cord, and the other in which there is compression of the cauda equina. The first, though rare, undoubtedly occurs, and when in the cervical region constitutes a cause for operation. In the second case the relief of pressure is as strongly indicated and is as successful as it is in the peripheral nerves.

The question of regeneration is the most important one in spinal-cord pathology. If the cord regenerates, the field for operative procedure is very extensive. Does the spinal cord regenerate?

It is well known that intramedullary fibers can be bruised and contused, and yet the symptoms which accompanied the original injury pass away almost entirely. But this, it is unnecessary to say, does not prove regeneration. It is a recovery from the original shock of the injury, and occurs, in my opinion, quite as often without as with the surgical relief of pressure.

The question of regeneration is this—Do nerve fibers of the spinal cord, which have once been actually severed in their continuity, regenerate? In no experiment on a cold-blooded animal has it been possible to divide the spinal cord completely and then secure a restitution of conducting function. Schmaus has shown that a divided spinal cord can be reunited by nerve fibers in case some of the blood-vessel-carrying tissue is left—that it is along this tissue that the new fibers push their way. But such fibers are few in number, embryonic in character, and form no connecting link of function between the two ends.

I am loath to go into a discussion of the recently reported cases of suture of the human spinal cord—they have in no instance been accepted by neurologists as proving regeneration, and I think the early enthusiasm of surgeons in regard to them has somewhat lessened of late. The neurological opinion, therefore, is mainly unanimous that regeneration of divided ends does not take place in the central nervous system.

THE TREATMENT OF FRACTURE DISLOCATIONS OF THE SPINE.*

By IRVING S. HAYNES, PH.B., M.D.,

NEW YORK.

Fracture of the vertebræ may occur independently of dislocation, and a dislocation without a fracture; yet the two are so often associated, and it is usually so difficult to diagnose one condition independently of the other, that it is found more convenient and practical to group these injuries of the spine under a comprehensive term. This is especially useful, as the treatment is similar in both conditions.

In practice we are confronted then with cases in which the spine has been damaged, with or without a concomitant injury to the spinal cord. If the injury is one to the spine alone, the treatment becomes much simpler than where there is associated with it a lesion of the cord.

We may deal with all such uncomplicated cases on the expectant plan; that is, by extension and immobilization in a plaster jacket. Should there be unmistakable evidences of a fracture-dislocation without cord involvement in any region of the spine, excepting the thoracic, the setting or reduction of such a fracture-dislocation may be attempted under general anesthesia without a cutting operation: bearing in mind, however, the imperative need there is of preventing a further displacement, due to moving the patient, with a resulting injury to the cord.

In the majority of these cases it will be found that, even with general anesthesia, reduction cannot be obtained without exposing the lesion through a free incision, and assisting the efforts at reduction by prying the articular processes into position, or by resecting the lower ones which oppose such reduction.

In the thoracic region, it is practically impossible to reduce the deformity through manipulation alone, and, therefore, it is better, if there are no cord symptoms, to treat the case by plaster jacket.

There is greater need of the application of an immobilizing dressing in the case of the injured spine than in fractures or dislocations in general, because, even if the cord is not involved at first, we never know when it may become so through a slipping of the injured vertebræ. Cases of sudden death are recorded where such a fatal termination has followed the voluntary or passive movement of

*Contributed to a symposium upon fracture-dislocations of the spine, at a meeting of the Medical Society of the County of New York, February 25, 1907.

the patient in bed. I had such a termination follow in a case of dislocation of the fifth cervical vertebra upon the sixth. Under ether anesthesia, by extension, counterextension, and manipulation, the dislocation was reduced and a plaster collar, including the chest and head, applied. This became so uncomfortable after twenty-four hours, and the patient was in such evident distress, that the cast was cut open along the front, but not removed. The man, who was much relieved, attempted to move his head, and died almost immediately.

It is quite a problem how to apply a plaster jacket in these cases of fracture-dislocations without subjecting the patient to too many risks. The plan I have used in some cases is this: In cervical injuries, either during or without general anesthesia, the patient's head and shoulders are brought beyond the edge of the table, and firm extension is made in a horizontal plane, maintained by a broad bandage behind the occiput and beneath the chin, fastened so it cannot slip and long enough to pass over one shoulder, across the back, and under the arm of a strong assistant, who is seated high enough to bring his shoulders a little above the level of the patient. The assistant braces his feet against the table on which the patient lies, and can maintain extension in such a position without fatigue for half an hour. For lower regions of the spine I have found the hammock support very satisfactory. With an ordinary hospital iron bedstead, where the crosspieces at the head and foot are about on a level, a sling can be improvised by passing several turns of a strong body bandage from one to the other, forming a support eighteen inches wide. The patient is placed on this face downward and steadied by assistants holding his arms upward and legs downward. The sagging of the support produces extension in the spine, and the support is included in the jacket from which it can be removed later.

If we do not wish to move the patient sufficient for the use of the above method, a safer plan is to make a wide Scultetus' bandage composed of thick canton flannel, well rubbed up with plaster mud. This is laid on the bed alongside of the patient, who is carefully rolled over, face downward, on to the bandage, and the ends of the bandage are carefully adjusted without disturbing the patient.

While there are many cases on record of fracture-dislocations of the spine without cord involvement, there are so many more in which this structure is damaged that in dealing with these conditions of the spine we must first consider the nature of the cord injury, and be guided by that more than by any other factor in the treatment we shall institute.

Even at the present day, valuable time is frequently lost in waiting to arrive at an opinion as to the exact nature and extent of the damage to the cord, and the dictum is quite universally accepted that, if the cord is completely severed by the scissor action of the vertebræ, then no operation is to be undertaken.

However, competent observers are quite unanimous in also declaring that it is often impossible to predict the exact nature or extent of the cord injury within a reasonable time. Being then "at sea" regarding the exact pathological state present it seems to me it is our duty to act at once. I mean by that as soon as shock has been recovered from, or the associated injuries, if any, have received adequate treatment.

The following conditions, in themselves, are recognized as justifying the operation of laminectomy, independent of whether the operation will or will not benefit the primary lesion in the spine:

(1) To remove pressure from bone, whether the posterior arch of a vertebra or only spiculæ of bone.

(2) To arrest hemorrhage, remove blood clots, and arrest an advancing paralysis.

(3) To allow oozing in traumatic edema of the cord.

(4) To provide drainage in septic conditions involving the cord.

The cord is such a fragile structure that contact with any foreign body, as serous exudate, blood clot, pent-up pus, or bony spiculæ or masses, speedily induces such grave pathological changes that its restoration to normal is impossible, unless such substances are removed at once and pressure is relieved. Without wasting precious time, then, in debating whether the patient before us has or has not a severed cord, I wish to urge immediate operation in every case of fracture-discoloration of the spine presenting symptoms of cord involvement, even if the severity of the symptoms seems to point to complete destruction of the cord. Mistakes in diagnosis are easy to make here; we cannot be sure of the extent of the injury to the cord for several days, and meantime the period has passed within which surgical interference might have obtained striking results.

Early operation will allow of the removal of the laminæ, or pieces of bone which are constricting or pressing into the cord, will furnish an opportunity to arrest hemorrhage, and so prevent pressure from a blood clot, and will provide an outlet for the edema, which often follows spinal injury.

The operation of laminectomy is not a difficult one, and not many instruments and assistants are needed. Let the incision be in the median line four to six inches long. Expose the spinous processes and laminæ for at least five vertebræ, the center one being the seat of the injury. With Rongeur forceps bite off the spinous processes at their bases, and open the spinal canal first in the middle line and then laterally, removing the laminæ and intervening ligaments. Do not waste time with any of the methods for plastic work in the removal of the spinous processes and laminæ, as they consume valuable time and their removal does not weaken the spine to any perceptible degree. Having exposed the cord, remove any projecting piece of bone pressing upon the cord, arrest hemorrhage by hot compresses or by ligature. Do not stop here; open the dura in the middle line and inspect the cord. If there be oozing of blood or serum, the first needs to be arrested by fine ligatures passed by a short, round, full-curved needle, the second to be provided for by drainage of the subdural space. Suppose the cord is severed; then opens a new phase of the treatment of spinal injuries. Many writers, but, I am glad to say, not all, advise us that in case the cord is severed operation is hopeless, because regeneration of a severed cord is impossible. I am not here to-night to debate the question. My reasons for advocating surgical treatment, even in such desperate cases, have been given at length in a previous publication, and I shall not bore you by repeating them to-night.

I respect the opinion of the men who assert that no operation is justifiable upon a severed cord because no regeneration is possible in its conducting paths after such a lesion. They know more about the histology, pathology, and reparative processes of the spinal cord than I do, but I will say this, and say it emphatically, that whether their kind of regeneration is possible or not, Nature has in a few cases of sutured cords effected some sort of union of the many severed fibers. When the cord has been

severed, and no attempt made to unite it, death has followed in every case in less than a year. In the few cases on record, five in all, where the spinal cord was sutured, and the ends brought together, one patient died in ten days as a result of the injury, the other four lived and were improving at the date of the report; one two and one-half years, and one over four years since the injury; and all of them showed unmistakable evidence of a less or greater restoration of functions between the sutured segments of the cord.

Having attended to the damaged spinal canal and its contents, the fractured or dislocated vertebræ have to be considered. Loose pieces of bone are removed, but those firmly adhered to ligaments and not encroaching on the spinal canal are not disturbed; a dislocated vertebra may be reduced by removing the locking articular processes as before indicated. The wound is then closed for primary union over a drain of several strips of rubber tissue or strands of silk-worm gut, and a plaster cast is applied as described above. The drainage should be removed in twenty-four to forty-eight hours. Treatment does not cease here, however, for if paralytic symptoms are present, then must massage, electricity, and passive motion be instituted and maintained for an indefinite period, depending altogether upon the condition of the patient.

Bedsores must be given careful consideration in prophylaxis and treatment. They are unquestionably due to pressure necrosis, and can be prevented by using a water bed and close attention to relieving pressure over the various bony prominences. Cystitis is a serious complication, often followed by a fatal pyelitis. Sterile catheterization with systematic irrigation of the bladder must be instituted early and maintained as long as necessary.

After three to four weeks of treatment in bed, if the patient's condition allows it, a new plaster jacket should be applied with a Sayre's extension tripod, or after the horizontal hammock plan, and this should be worn, changed as often as necessary, for several months; or if a less rigid support is permissible, the Taylor spinal brace can be adjusted. Such support should be worn for at least a year after a laminectomy for a fracture-dislocation.

1125 Madison Avenue.

PHOTOTHERAPY IN NERVOUS DISEASE.*

By A. D. ROCKWELL, A.M., M.D.,

NEUROLOGIST AND ELECTROTHERAPEUTIST TO THE FLUSHING HOSPITAL—FORMERLY PROFESSOR OF ELECTROTHERAPEUTICS IN THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL, EX-ELECTROTHERAPEUTIST TO THE WOMAN'S HOSPITAL IN THE STATE OF NEW YORK, ETC.

When invited some time ago to take part in this symposium and present a short paper upon some topic that was especially interesting me in the domain of neurology or psychology, I at once fixed upon the subject of phototherapy. Not that I had any very large or notably valuable experience along this line, but it so happened that I had recently installed in my office an incandescent light apparatus of considerable power, and, like the child with the new toy, it was superseding in immediate interest other and more familiar physical method. I shall not attempt to emulate the too common tendency in the exploitation of physical methods of treatment, by claiming for light therapy exraordinary and uniformly successful results. Nevertheless there is much truth in the alliterative phrase—light and life, darkness and death—and in the artificial incandescent electric light we have a method of utilizing powerful luminous and calorific effects, and to a less extent actinic effects as well, second only to the source of all light and heat—the sun. It is well to have a definite conception as to what phototherapy means. It means light treatment. For practical purposes the rate of vibration is all-important in classifying the different forms of vibratory energy.

The slower rates which influence the auditory nerve and are translated into sound are unavailable for therapeutic use. As the rates increase in frequency we get the perception on the thermic sense as heat, and still further increase gives us light—the visible spectrum. Beyond the visible into the invisible region of the spectrum we get the ultra violet and the *x*-rays. While there are no sharply defined lines between these different rates of energy, we are nevertheless able to comprehend the actual difference between sound, heat, light, and electricity by our senses and the ultra-violet and *x*-rays by chemical means.

In the earlier experiments by Finsen and his followers, the term phototherapy came to be used to include as much or more of the invisible rates as the visible, notwithstanding the fact that what is invisible can hardly be called light.

Strictly speaking, then, this term should be used to include the visible spectrum only. In therapeutics, light is utilized by three methods: Sunlight, the arc light, and the incandescent electric light. Light is essentially the same from whatever source obtained, but as a matter of convenience it is important as to how and where we get it. The combined luminous, calorific, and actinic rays of sunlight are more powerful than from any artificial source, but the obstacles in the way of its general utilization are obvious. It is with the incandescent (sometimes called leucodescent) lamp light, with its powerful heat and light rays, that I have to do in this paper. The ultra-violet ray to be sure is a part of the incandescent light, but it is unavailable for use in the mechanism of the incandescent light apparatus because of its inability to penetrate glass. And yet the incandescent light is by no means devoid of chemical power, for it is sufficiently rich in the blue, indigo, and violet frequencies, to the passage of which glass is no hindrance. The arc light more nearly approaches concentrated sunlight in its actinic and luminous power, but is deficient in heat rays, and its chief value lies in its localized and superficial action, which in certain conditions, as Finsen so ably demonstrated, is powerfully curative. The incandescent light therefore is manifestly inferior in some respects to either sunlight as used by the Finsen method, or to the arc light. It is weaker in chemical effects, and its luminous power is also inferior to the other two, but the heat emitted is far greater, and in my experience this combination of calorific and light effects renders it far more valuable than the arc light in its general constitutional influence, and in the relief of local painful conditions. That the higher rates of vibration (the ultra violet) are useless for the production of constitutional effect is due to the fact that they penetrate the body only under pressure or other methods of producing dehematization of the skin, and then but slightly, while the combined rays act efficiently to a great depth, even passing completely through the tissues, as evidenced by their action on a sensitized plate placed on the opposite side of the body. The incandescent light bath differs in its heat, to say nothing of its light effects, from the ordinary hot air bath, in that in the former the heat is communicated to the body through the transmission of radiant

*Read before the Medical Association of the Greater City of New York, February 18, 1907.

energy—which leaves the surrounding air but slightly affected. This is easily demonstrated by interposing an opaque substance between the source of light and heat and the body, when all sensation of heat ceases. The radiant energy penetrates the body and as it meets with the resistance of the more or less dense bodily structures is converted into heat. In the hot air bath, on the contrary, the heat is derived from the air, and while more depressing in its effects is far less penetrating than radiant heat, and is inferior in its physiological and therapeutic effects.

The superior physiological effects of radiated heat, as compared with heated air, would seem to consist in its more powerful rubefacient effect upon the skin with accompanying dilatation of the superficial vessels. This relaxation of the superficial vessels being unaccompanied by any appreciable heating of the surrounding air can be maintained for a long time without discomfort, and is followed by interesting alterative and reconstructive effects through its influence upon metabolism. Perspiration is induced more quickly by radiant heat than by most other methods. In the Turkish hot-air bath, some twenty minutes are necessary to excite active sweating, while exposure to a bearable degree of radiant heat stimulates the skin to the point of perspiration in five minutes or less. This more rapid result is accounted for by the stimulating effects of the light rays upon the peripheral nerve endings.

But one of the most interesting evidences of the increased oxidation and tissue changes induced by this form of radiant energy is the increase in the elimination of carbon dioxide. As compared with the hot air bath it has been found that the increase of the natural oxidation of the body as indicated by the elimination of carbon dioxide was four times greater in the light bath.

Light acts on the blood, increasing the hemoglobin-carrying power of the red corpuscles, and is decidedly bactericidal, although this destructive influence upon microorganisms must be attributed in far greater measure to the action of the ultra violet —the invisible rays. As the nervous system is the only route through which sensations are conveyed, it follows that light and heat effects should be classed as a nerve stimulant or a nerve sedative according as the degree of their intensity results in an increase or reduction of energy.

The function of the nerve endings becomes either more keenly alive or their perceptive powers are dulled according to the kind, and the duration and intensity of the physical agent employed. An increase, decrease, modification or destruction of the nervous influence are demonstrable changes in innervation that follow thermic and chemical stimulation, and it is by this inhibition or modification of nerve conduction that the combined thermic, luminous, and chemical effects of light influence the hyperesthesias, the anesthesias, and pain in general. Since the nervous system stimulates and regulates the functional processes, the reflex effects of local peripheral stimulation are often seen in remote parts.

All physical therapeutic agencies are, in fact, primarily irritants. Indeed life, with its vital processes, depends on constant irritation and physical forces applied to the body can be believed to be transformed into vital cell energy. At all events it is well understood that deprivation of irritation so that the normal functional activity is restricted and held in abeyance results in functional weakness, while, on the other hand, local or general physical irritants stimulates and strengthens, or depresses and weakens, according as they are applied in moderation and adequately, or in excess.

In entitling this paper "Phototherapy in Nervous Diseases," I would by no means thus limit it, although the condition of the nervous system is largely responsible for many a disease that is not classed as nervous.

The principles on which is based the therapeutics of light and heat are fundamentally very much the same as govern in the application of other physical methods of treatment. They unquestionably influence metabolism and necessarily the processes of excretion and secretion.

The circulation is, of course, profoundly influenced, and when we consider the intimate circulatory relationships between the skin and the various internal organs of the body, it is no very difficult matter to appreciate in how many ways benefit may be derived from the play of these energies upon the periphery. If the vessels of the skin when distended are capable of holding, as is asserted, one-half the whole amount of blood, it is evident that this distention must greatly relieve congested parts, with which they are in immediate connection.

It relieves nerve pressure and pain by exciting the activity of the circulation through congested areas, resulting in a sort of circulatory drainage, as it were.

This is the primary and perhaps most important effect of the application of light and radiant heat. More prolonged and intense applications are still effective in the dissipation of local hyperemias, but not so much it is believed through an increased activity of circulation as by inducing a secondary contraction of the arterioles.

To enumerate the many pathological conditions for which the light treatment has been found to be of service would make a long list, and it is beyond the scope of this paper to detail cases, although many of a most interesting and convincing character might be related.

But this much may be said. As a rule, whenever and wherever pain exists, whether in the form of the neuralgias or neuritis, or pain of the rheumatic or gouty type, a judicious application of the light bath is pretty certain to give temporary relief, and successive applications in a large proportion of cases are followed by permanent relief. With tuberculosis I have had no experience, but much has been claimed for it, and I am not prepared to dispute the claim that in chronic localized tuberculosis much good may result. Some little experience I have had in the application of these powerful concentrated light and heat rays as a general tonic and an aid to nutrition, especially in children convalescing from acute disease or with a poor inheritance of vitality.

In the toxemias and the toxic neuroses, the therapeutic value of light energy is beyond question.

This I can affirm, both from my own experience and the observed results of Dr. T. Crothers in a series of a thousand treatments given to patients in his sanatorium. In the toxic neuroses and the palsies they were found to be of the greatest benefit—far preferable to hot air and vapor baths. In my own cases I have found that the benefit derived from the light bath was often greatly enhanced by supplementary physical methods, such as static electric high-frequency currents and general faradization.

In conclusion it may be said that the basis of the action of the light bath in disease would seem to be these four:

1. Its bactericidal power.

2. As a promoter of tissue metabolism.

3. Its influence in increasing the hemoglobin-carrying power of the red corpuscles.

4. Its analgesic properties, due to its power to relieve blood pressure through induced congestion of superficial vessels, and to its infinitely rapid vibratory action on the nerve units of the body.

The Sydenham, Madison Avenue and Fifty-eighth Street

THE EARLY MOBILIZATION OF PATIENTS AFTER MAJOR GYNECOLOGICAL OPERATIONS.*

By ABRAM BROTHERS, B.S., M.D.,

NEW YORK.

Adjunct Professor Gynecology New York Post-Graduate School; Visiting Gynecologist Beth Israel Hospital.

New methods which aim at overthrowing customs established for centuries must expect to encounter obstacles of such magnitude that the voice of a single individual counts for little and may well be likened to the solitary voice in the desert. The plea must rather be for a dispassionate hearing, and, if converts are to be made, the solitary voice must be backed by logic in its argument and a sufficiently large number of experiences to give the foundation-stones of the argument the strength and firmness of granite.

In the *Journal of the American Medical Association* for August, 1899 (xxxiii., pp. 454), Ries of Chicago, in a short article, announced that, after giving the method a trial of four years, he now placed little or no restrictions in the movements or diet of his patients after vaginal celiotomy or abdominal section. They were permitted to turn around and sit up in bed and out of bed as soon as they were fairly able. In the discussion, Manley, Wiggin, and Schaefer agreed in the main with the new ideas set forth, but Bonifield insisted that the experience of ages was not to be thrust aside in a minute. No attention apparently was given to this communication, and probably the majority of surgeons regarded the proposition as absurd, if not insane or criminal. Fifteen years ago Boldt was ordering his vaginal celiotomy cases out of bed in twenty-four hours, but only two and one-half years ago did he take up the question in connection with abdominal work, and, after a fairly large experience with it, announced his confidence therein at the Birmingham meeting of the Southern Surgical and Gynecological Association; and later, at a meeting held a year ago, of the New York Obstetrical Society. At a subsequent meeting a strong paper attacking this method was written in a cleverly sarcastic vein by one of the Fellows, Dr. Franz Foerster, on which occasion, in spite of insisting on the correctness of his position as based on his experiences, the feeling of the meeting seemed to be very strongly against Boldt. One of the Fellows remarked that Boldt's position was untenable, if an accident occurred, in case of a malpractice suit, as no colleague could be found who could conscientiously support him in his contention that such early mobilization was proper after abdominal section.

The writer confesses that nobody regarded this proposition of early mobilization after major operations with greater suspicion and scepticism than himself. A certain thrill of horror unconsciously passed through his frame at the thought of a laparotomized patient being taken in the arms and sat upright in a chair within twelve hours after operation. There seemed to be an element of unjustifiable brutality in the procedure. But watching the cases of my friend, Dr. Boldt, and noting the improved morale which set in almost from the moment the patient emerged from the anesthetic, and the rapidity with which convalescence progressed, I felt that I owed it to myself and to my patients to give the method a cautious trial. I beg to state right here that I have never yet had the courage, nor have I seen the necessity, for getting my patients out of bed before forty-eight hours, and the larger number of my patients were not allowed out of bed until the fifth, seventh, or eighth day. This agrees with the plan adopted by Ries, who does not permit any of his patients to leave the bed until at least three days after operation, and others not until after removal of the stitches on the sixth to the eighth day; but all are permitted to move about in bed as soon as they want to. Even this, however, anticipates the convalescence by at least one or two weeks, and is in itself, from my point of view, a vast stride in advance over the method generally in vogue, by which patients are kept in bed from fourteen to twenty-one days.

On what basis is the method of early mobilization to be granted a fair and dispassionate hearing? The statistics of Ries, Boldt, Chanler, and myself now easily cover 1,000 laparotomies; and in no case has an accident occurred which can be fairly attributed to the early mobilization of the patient.† In the paper of Ries, above alluded to, he claims to have had only one death in 100 vaginal celiotomies (a septic case), of which 60 were hysterectomies, and to have had no case of vaginal hernia or hemorrhage. The Mayo brothers, I understand, place their patients in an upright position after operations on the stomach and gall-bladder, as soon as the patient emerges from the anesthetic. Moynahan, in his work just published on "Abdominal Operations," advises the same procedure "after all operations upon the stomach and after some upon the gall-bladder." This writer adds: "I find that it is a general custom to keep all patients in bed much longer than is necessary. If all is going well, the sooner the patient is up the better." He permits an appendectomy patient to be out of bed in six or seven days, and to return to light work in a fortnight. A medical man was seeing patients on the fifteenth day, after a gastro-enterostomy and cholecystotomy, and no ill effects followed. In the Medical Record of November 24, 1906, Marshall and Quick, reporting 100 laparotomies with two deaths, write: "In all simple laparotomy cases with small incisions, and in which extensive work is not done upon the viscera, the patients are placed in a sitting posture upon the third or fourth day, and permitted to be up upon the sixth day, usually leaving the hospital before the tenth day."

It is a good rule that combatants look their opponents squarely in the face in order to meet properly and victoriously every variety of thrust or blow. Let us, then, seriously and in cold reason look over the ground and consider the objections to the early mobilization of patients after major abdominal operations. What are the dangers after laparotomy?

Among the immediate dangers, that of post-operative shock or collapse easily ranks first. As a matter of fact, many cases reported formerly as shock were simply cases of secondary hemorrhage. I have known even a cigarette drain in the abdominal wound to fail to direct blood to the exterior, after

* Presented, by special invitation, at the meeting of the Southern Surgical and Gynecological Association, held on December 11, 1906.

† Since the above was written I have learned of one case in which the laparotomy-wound reopened. This was attributed to the poor quality of the adhesive plaster used

extensive secondary hemorrhage, and this case was treated for a time as one of primary shock due to the traumatism of operation. On the other hand, debility resulting from protracted invalidism, excessive hemorrhage during operation, prolonged anesthesia, and traumatism, or excessive handling of the intraabdominal viscera, may lead to true shock. Such cases of shock are excluded from the category of those in which early mobilization is to be thought of. On the other hand, early mobilization does not tend to develop shock according to the experience, up to the present, of those best in position to know.

Hemorrhage is not to be feared in the hands of competent surgeons. Our knowledge of ligature materials and technique is to-day so precise that bleeding from loosening of such ligatures is hardly to be expected after the lapse of twelve hours—unless other complications, such as cough or vomiting of a severe type, are present. As a matter of fact, no cases of hemorrhage have been noted in the thousand cases referred to, and the operator need have no fear from this score.

Reopening of the abdominal wound with more or less evisceration, I have met with three or four times during former years. Patients who are delirious or maniacal may tear away dressings, and with the finger-nails reopen laparotomy wounds. This happened once, I recall, after a cesarean section followed by complete hysterectomy, which I did on an Italian woman who entered my service in an advanced stage of sepsis, with a large cervical fibroid blocking the pelvic outlet, the gangrenous cord being prolapsed several inches and presenting at the vulvar orifice. This woman, in her maniacal state, tore open her wound, and the intestines lay on the surface of the abdomen. After carefully washing them and returning them to the interior of the abdomen, the laparotomy wound was again sutured, and the woman made a good recovery. Other cases of reopening of the abdominal wound with more or less evisceration occurred as the result of excessive vomiting or associated with severe bronchitis or pneumonia. I do not recommend taking such patients out of bed. Beyond the raising of the patient in bed during a pneumonia or bronchitis, no further efforts at mobilization should be made. As a matter of fact, it will be shown later that immobilization on the back is distinctly bad treatment when bronchial secretions are in danger of accumulating in the air-tubes or alveoli. As regards the risk of reopening of the abdominal wound in the absence of these complications, most operators who close such wounds in three or four layers have learned to ignore it. In the early mobilization of patients, Ries is wrong when he allows his patients to move about and sit up unbandaged, even if he does use strips of adhesive plaster in order to approximate the edges of suppurating wounds with the object, incidentally, of reinforcing the abdominal wall. The position of Boldt is far more logical, in that he immobilizes the abdomen by means of a bandage of adhesive plaster surrounding the whole body, which holds it in a vise-like grip, before he permits his patients to be moved about. I have adopted Boldt's method and regard his plaster as a most important safeguard against any possibility of reopening of the laparotomy wound. After a vaginal hysterectomy I have known of one fatal case in the hands of a colleague, in which early mobilization seemed to be partly responsible for adhesions and angulation of the intestines. In this case the house surgeon removed the vaginal drain without consulting the operator at the end of twenty-four hours. My own experiences, however, with vaginal celiotomy, including hysterectomy, have been free from accidents.

Vomiting, distention, and inability to move the bowels, are not necessarily contraindications to the early mobilization of patients. Indeed, some of us are convinced that moving the patients and getting them early in an upright position in a chair even aids intestinal peristalsis, and the early removal of gases and intestinal contents with relief of belching and vomiting. Indeed, Ries says that not only is intestinal peristalsis assisted by early mobilization and early feeding, but that adhesions are prevented from forming, and that the easy and spontaneous movement of the bowels is thereby assisted. In a case recently operated on by the writer, the indication for the laparotomy was the breaking up of old adhesions left after a previous operation for ectopic gestation. This woman left her bed in forty-eight hours and began to walk about. She left the hospital free from the old pains.* Of course, conditions of anemia of the brain, great debility, etc., would induce the careful surgeon to weigh all of the circumstances and act slowly before getting such patients up.

Interference with the primary union of the laparotomy wound is not a result of early mobilization. If suppuration of the wound occurs, the fault lies with the operation or the ligature materials. Drained wounds are not proper cases for early mobilization until at least a week has elapsed and the drain has completely or nearly been dispensed with. Otherwise, there is risk of hernia. A rapid pulse, even without elevation of temperature, may indicate wound suppuration, and is a contraindication to early mobilization.

Thrombosis and embolism constitute the greatest and most serious of the more remote risks following laparotomy, and offer the gravest objection to those who are most earnestly opposed to the idea of early post-operative mobilization. From the excellent chapter by Frazier, in the first volume of Keene's "Surgery," just published, I abstract the following facts and statistics.

A thrombus is defined to be a mass, the component parts of which are derived from the blood, formed in the heart or peripheral vessels. Infection is the predominant factor in the majority of cases of thrombosis which come under the surgeon's care. Retardation of the blood current is a predisposing or contributing cause. Unless in cooperation with some other condition, as a lesion of the vessel wall, or the presence of organisms, it cannot give rise to thrombosis. Arterial thrombosis is more common in the lower extremities, is due to embolism or traumatism, or is associated with disease of the arterial walls (endarteritis or arteriosclerosis), and when present is usually the result of infection or chronic disease. In some instances, both arterial and venous thrombosis exist at the same time. The femoral vein is almost invariably the seat of venous thrombosis, and the majority of cases occur on the left side.

Albans alludes to four etiological factors: (1) Disturbances before operation (such as heart lesions, varicose veins, exhaustive, prolonged decubitus, presence of abdominal tumors); (2) disturbances at time of operation (such as chilling and exposing of abdominal contents, traumatism of vessel walls); (3) effect of anesthetic on the heart; (4) topographical relations of the vessels (thus an overloaded sigmoid might press on the left iliac vein or the iliac artery might press on the iliac vein).

Clark attributes such a thrombophlebitis to the

*I have since then operated in a second case for this indication and had the patient sitting in a chair after forty-eight hours.

effect of traumatism exerted upon the deep epigastric vessels during the course of a laparotomy, as a result of traction on the edges of the wound. He thinks that the primary thrombosis may start in the deep epigastric vein and be slowly propagated along the line of the vessel until it reaches the external iliac vein, whence it gives rise to a retrogressive thrombus in the femoral vein.

In Sonneburg's clinic thrombosis was met twenty times in 1,000 operations for appendicitis. Fourteen of these occurred in interval operations, which are ordinarily nonsuppurative conditions. In 3,000 laparotomies Clark found records of only thirty-five cases of thrombosis. Schenck in 7,130 gynecological operations found that twenty-five cases of thrombosis occurred after hysterectomy, and nine after ovariotomy. Albans notes fifty-three cases of thrombosis in 1,140 laparotomies and twenty-six occurred after "clean" operations. In the service of W. K. Polk at Bellevue Hospital, between the years 1895-1902, there was not a single record of thrombosis or embolism in 103 abdominal or vaginal hysterectomies. At the Beth Israel Hospital, from October 1, 1905, until October 1, 1906, in nearly 350 abdominal sections, we had four cases of femoral thrombosis. In three of these cases the operations were done for suppurative appendicitis and, in the fourth, for a broad ligament abscess. None of these patients at Beth Israel Hospital, and none of those referred to in the foregoing statistics, to my knowledge, was submitted to early mobilization. On the other hand, the thousand cases treated by early mobilization present only two cases (one of Boldt and one of Ries), or possibly three, in which a thrombosis occurred. As I saw Boldt's case, I have my doubts as to whether the mild phlebitic condition had really anything to do with the post-operative mobilization—occurring as it did three weeks after the operation in a very active young lady.

In Sonneburg's 1,000 cases of appendicitis three cases of embolism are noted with two other fatal cases, in which embolic pneumonia was supposed to have been present. Pulmonary embolism is said to occur much more commonly after gynecological than after general surgical operations. Albans, in 1,140 abdominal operations, found twenty-three cases of pulmonary embolism. Lotheisen, in sixty-six cases of pulmonary embolism, found forty to be secondary to phlebitis and thrombosis of the veins of the lower extremities; next in frequency come those which start from thrombosis in the pelvic veins in the puerperium, or after operations upon the pelvic organs. In 236 operations for uterine fibroid, according to Burkhard, twelve cases of embolism occurred. Of the fifty cases of abdominal section which were subjected to early mobilization, in my services at the Beth Israel Hospital, Post-Graduate Hospital, and elsewhere, all the patients recovered. I met no cases of embolism or thrombosis, and only one pneumonia (with pneumococci in the sputum). Neither Reis nor Boldt met with accidents of this kind in their 885 cases, and in my case the patient was distinctly exposed on a very cold night to a draught from a window, which could not be closed, at the head of her bed.

Many surgeons have a grave fear of late or dedelayed shock, and oppose early mobilization for this reason. During the past year I met two such cases in my hospital work in which the patients were confined to their bed. In the first case a purulent collection was found in Douglas' sac after an apparently spontaneous abortion. This was incised and drained in the usual manner on December 25. Excepting a rapid pulse, everything was doing nicely, with temperature (formerly 103° F.) at the normal, when on January 2, with the patient still in bed, she went into sudden collapse without any evidence of pain. Vomiting set in, temperature dropped to 94° F., and the pulse became imperceptible. After free stimulation, including intravenous infusion of saline solution, she gradually emerged from the shock and went on to a spontaneous and complete recovery. The second case occurred forty-eight hours after a radical abdominal operation for suppurating adnexa, in which vaginal drainage was instituted. Without having been moved in bed, because of a rapid pulse, the woman passed suddenly into a condition of profound shock and was brought back to life only by vigorous stimulation and an intravenous saline infusion. I consider the possibility of secondary or delayed shock as one of serious importance, and one which should be borne in mind in the cases in which we are urging early mobilization. I have always regarded a rapid pulse after laparotomy, even in the absence of a distinct febrile movement, with suspicion. Both of these patients were not disturbed on that account, and perhaps the fortunate outcome in both may have depended on that circumstance.

Up to a recent period of time post-operative pneumonia was thought to be the result of the anesthetic. Moynahan accounts for its occurrence in five different ways. He claims, first, that the immobilization resulting from the unconscious protection of the wound area by the patient results in the accumulation of bronchial secretions in the lung. Deep breaths are avoided and the air-passages are not cleared by the act of coughing. This results in irritation and waterlogging of the lungs by retained secretions. The second cause is chilling of the patient's body during or shortly after operation. The third cause is the inhalation of septic matter into the lungs. The fourth cause he attributes to septic emboli derived from the field of operation. The fifth cause he attributes to a long continuance of the Trendelenburg position. What argument could be more potent and favorable to early mobilization than the first reason which Moynahan above gives as a predisposing cause to post-operative pneumonia? It has long been recognized by medical men that the sitting position in bed conduces, in great measure, toward a favorable result in cases of pneumonia. Why not apply the same principle, in appropriate cases, to the avoidance of this complication after operation?

While early mobilization is possible, and, according to my conviction, beneficial in a large number of cases after laparotomy, I believe that the exact limitations of the method have not as yet been drawn. As I do not pretent to be an extremist, I have laid down for my own guidance the following contraindications to the early mobilization of these patients: (1) Shock or collapse preceding, during, or subsequent to operation; (2) organic lesions of the heart, kidneys, or blood-vessels; (3) debilitated or senile patients; (4) rapid heart action after operation, with or without rise of temperature; (5) persistent elevation of temperature, after operation, from any cause; (6) signs of peritonitis; (7) hernia operations; (8) complications like pneumonia, diarrhea, dysentery, etc.; (9) after suspension, fixation, and prolapsus operations; (10) in vaginal plastic operations (especially on the perineum) associated with laparotomy; (11) in drained and suppurating abdominal wounds.

I believe in early, gradual, and rational mobilization. To place a patient after a laparotomy in a chair twelve hours after the operation, seems to me to be one extreme: to keep the same patient on her

back in bed during three weeks, with no reaction present, seems to me to be the opposite extreme. That patients recover under both methods does not prove that either is the one to be generally followed. Nor do I regard successful results after early mobilization in the light of surgical curiosities, or even as experiments. My own plan is to let the patient severely alone during the first twenty-four hours—the nurse merely is allowed to place the pillows comfortably under the patient's head and shoulders. If all goes well on the second or third day, the patient may be sat upright in bed for a few minutes, supported on the nurse's arm; later by a few hours she may be propped up by pillows in a sitting position during a quarter of an hour. The following day she may be in this sitting posture in bed for an hour in the forenoon and an hour in the afternoon. After that she can be gently placed in a chair for a reasonable period of time during each succeeding day. While these movements are being carried out under the orders of the physician, the nurse must keep a close watch on the patient's pulse. With the first evidence of faintness or rapid pulse the patient is returned to bed and no further efforts at mobilization are made for several days. While I have been obliged to desist from and postpone active mobilization in a number of my cases, because of wound disturbances, I have had no fatal complications, and I have been satisfied that wound suppuration, when it did occur, was independent of the movements and dependent solely on infection from purulent matter soiling the wound edges at the time of operation, or from ligature material.

Early mobilization is possible when the plaster binder of Boldt is on the patient. This plaster surrounds the body of the patient, and the serrated ribbons so overlap each other in front, that the abdomen is supported from below upwards and held in a vise-like grip. From the onset these patients are allowed to drink freely of water, albumin water, peptonized milk, beef extracts, and orange juice. Moynahan says: "It seems to me not improbable that death took place in some of my early cases literally from starvation." After twenty-four hours Ries and Boldt give their patients meat, bread, and vegetables, insisting, however, on thorough mastication.

To sum up, early mobilization, from the writer's point of view and experience, tends to overcome ordinary vomiting, accumulation of intestinal flatus, and bronchial irritation from retained secretions in the air-passages. Instead of contributing additional risks to the possibilities of thrombosis and embolism, he thinks that, in the absence of septic infection, the early moving about of these patients actually tends to reduce these risks. The morale of these patients is always wonderfully improved, and a tendency to debility, hysteria, and mental states of depression and anxiety correspondingly diminished. The total result, therefore, is an earlier and more pleasant convalescence. According to Ries, the method prevents muscular atrophy, conduces to a rapid recovery of strength, and permits of the discharge of these patients from the hospital in about twelve days.

To prove that neither the character nor the magnitude of an operation necessarily debars early mobilization—the objectionable conditions referred to being absent—I append a few cases selected at random from my notes.

Case I.—Patient of Dr. Charles L. Antony. Patient in a chronic pyemic condition from a suppurating fibroid tumor reaching up to the level of the umbilicus. She had lost some thirty or forty pounds in weight, and was in a debilitated condition at the time of operation. Abdominal hysterectomy done at Beth Israel Hospital on November 20, 1905. Patient was out of bed on the seventh day and made a progressive and uneventful recovery.

Case II.—Patient of Dr. Martin Goldberger. Case of bilateral gonorrheal pyosalpinx. Both pus sacs with purulent ovaries, removed with ventrofixation, at a private sanatorium on July 10, 1905. Little suppuration in lower angle of wound. Patient out of bed at end of a week. Got married later and was well when last heard from.

Case III.—Patient of Dr. I. A. Lehman. Laparotomy for ruptured ectopic gestation at St. Mark's Hospital on January 3, 1906. Out of bed on the eighth day, and at home on the tenth day. Seen six months later at my office with scar in ideal condition.

Case IV.—Patient of Dr. Max Ghertler. Laparotomy at St. Mark's Hospital on February 2, 1906. Appendectomy and right oophorectomy. Out of bed on the fourth day. Sent home on the thirteenth day. Scar perfect nine months later.

Case V.—Patient of Dr. Joel Grosner. Laparotomy at St. Mark's Hospital for bilateral pyosalpinx with right-sided ovarian abscess. Removal of pus sacs complete. Out of bed on fifth day. Sent home on the tenth day. Called at my office on the thirteenth day the picture of perfect health.

Case VI.—Patient of Dr. H. O. Carrington. On June 19, 1906, at Post-Graduate Hospital, supravaginal hysterectomy for large fibroid tumor of the uterus. Out of bed on the fifth day. Sent home on the tenth day.

Case VII.—Service case at Post-Graduate Hospital. Admitted in a cyanosed condition with high temperature and rapid heart action. Ruptured abscess suspected and operated a few hours after admission. Large double tuboovarian abscesses found on abdominal section done June 30, 1906. Rupture during operation. Cigarette drain gradually removed during six days. Out of bed eighth day. Sent home on fourteenth day. Examined four months later and scar found to be perfect.

Case VIII.—Case of Dr. M. Cisin. Total abdominal hysterectomy for large fibroid uterus with elongated cervix at Beth Israel Hospital on July 3, 1906. Out of bed on eighth day and sent home at end of two weeks.

Case IX.—Service case at Post-Graduate Hospital, operated July 27, 1906. Laparotomy for ruptured extrauterine pregnancy. Wound closed without drainage. Patient out of bed on the fourth day, and sent home on the tenth day.

Case X.—Service case at Post-Graduate Hospital. Had had laparotomy done five months previously. Second laparotomy, August 2, 1906. Removal of right adnexal inflammatory mass. Exsection of thickened and adherent omentum. Separation of extensive adhesions to abdominal wall and elsewhere. Exsection of blood cyst from left ovary, amputation of outer third of this tube and suture of ovary to stump. Out of bed on seventh day. Presented perfect scar two months later.

Case XI.—Service case at Post-Graduate Hospital. Woman with six months' baby at the breast. Laparotomy on August 18, 1906, removing a large left-sided multilocular ovarian cyst. Partial oophorectomy of left-sided cystic ovary. Ventrosuspension. Resumed nursing forty-eight hours after the operation. Out of bed on the eighth day. Three months later presented ideal abdominal scar.

Case XII.—Case of Dr. Aaron A. Mendel. Vaginal hysterectomy for carcinoma uteri at Post-Graduate Hospital on September 7, 1906. Out of bed on the seventh day. Left for home on the tenth day.

112 East Sixty-first Street

THE PROGNOSTIC VALUE OF THE DIAZO REACTION IN TUBERCULOSIS;

WITH INTERESTING OBSERVATIONS AS TO RACIAL DIFFERENCES IN WHITES AND BLACKS.*

By JOHN ROY WILLIAMS, M.D.,

GREENSBORO, N. C.

LATE BACTERIOLOGIST, PATHOLOGIST AND ASSISTANT HOUSE PHYSICIAN, WINYAH SANATORIUM, ASHEVILLE, N. C.; MEMBER GUILFORD COUNTY MEDICAL SOCIETY, NORTH CAROLINA MEDICAL SOCIETY, AMERICAN MEDICAL ASSOCIATION; HONORARY VICE-PRESIDENT AMERICAN INTERNATIONAL CONGRESS ON TUBERCULOSIS; LECTURE STAFF, TRAINING SCHOOL FOR NURSES, ST. LEO'S HOSPITAL, GREENSBORO, N. C.

THE value of the diazo reaction as a prognostic sign in tuberculosis is no longer a disputed question. For the past ten years it has been subjected to the most critical observation, until now it is generally accepted as a fact that the persistent presence of a marked diazo reaction in tuberculosis means an early fatal termination. There has been much literature published on this subject in the last eight years, from which I gather the consensus of opinion is that it is a bad prognostic sign.

In 1899, Michaelis[1] reported his observations in 106 cases of tuberculosis, as to the value of the diazo reaction as a prognostic sign. Of these 106 cases, the diazo reaction was found in 75, and was absent in 31. Of those patients giving the reaction, 89 per cent. either died or grew worse while under his observation. Of those not giving the reaction, 87 per cent. gave good results with treatment.

Karl von Ruck[2] does not give a hopeless prognosis in every case where the diazo reaction is present. He has seen a weak reaction disappear permanently upon the administration of hot water internally along with mild diuretics.

Wood,[3] of St. Luke's Hospital, New York, reports 230 cases of tuberculosis. Fifty-two of these died in the hospital. Of these 52 cases, 90 per cent. gave a persistent, strong diazo reaction.

Upson[4] reports that his experience goes to show that the persistence of the diazo reaction in a known case of tuberculosis is of considerable value as an unfavorable prognostic sign.

I wish to add to the above opinions my own, which has been formed after the observation of 100 cases of tuberculosis which have come under my care. Until I came to Greensboro, my experience in tuberculosis work had been confined to the observation of cases which were under the care of my father, Dr. John Hey Williams of Asheville, N. C., and of Dr. Karl von Ruck of the Winyah Sanatorium, Asheville, N. C. Since neither of these men treat the disease in the negro race, I never had the opportunity to observe the disease in the blacks. Since coming to Greensboro I have made no distinction in my practice as to race, and have observed tuberculosis in its various stages in both whites and blacks.

It is my custom to make a careful and complete urinary analysis in every case, and the diazo reaction is one thing in particular that I always look for, believing its presence or absence a valuable prognostic sign. My experience along this line has been such as to confirm the opinions of those above quoted, that is in the white race. As to the negro race, my observations are peculiarly interesting, especially in that I have never seen any report bearing upon the diazo reaction in the urine of the tuberculous negro.

Of the 100 cases which have come under my care, 73 have been in the white race. Of these, 38 were advanced cases, with 23 giving a diazo reaction. Of those giving a diazo reaction, the diazo disappeared in 5 cases, upon the application of hot water and salol internally. All of these gave a weak reaction at the start. Of these 5 cases, the diazo reappeared in 3, persisted, and the disease grew worse. The two patients in whom it did not recur improved under treatment, are still living, and there is an apparent arrest of the disease. The other 18 patients continued to give a marked and persistent diazo; all of them either died or grew worse.

In my second stage cases, I had one which, upon admission to treatment, gave no diazo reaction. During the first five months of treatment, improvement was rapid. This patient interrupted treatment for one week, going to her home in Georgia. During her absence, she contracted a very severe cold, which lighted up her trouble to the extent of marked severity, a caseous pneumonia developing, and a marked diazo reaction appearing, which remained persistent. She rapidly grew worse, and within six months from the time the diazo appeared she died.

On admission, one of my first stage cases gave a weak diazo. This patient gave a history of typhoid fever just two months previous to my seeing him. He left Greensboro, going to the mountains of Virginia. Upon his return, a urinary analysis showed an absence of the diazo reaction. There was not enough tuberculous trouble, and it had not progressed to the stage necessary to produce a diazo, and I believe that the reaction in this case was due to a persistence from the typhoid fever.

So, of my white patients I got a diazo in 23 of an advanced stage, 21 of whom either died or grew worse. One patient in the second stage developed a diazo at the fifth month, grew worse and died. One first stage case presented a diazo on admission, which I believe to have been due to persistence from typhoid fever, and which disappeared without treatment. Eliminating this last case, I got a diazo reaction in 24 white patients, 22 of whom either died or grew worse. So in 88.5 per cent. of my cases giving a diazo, the prognosis was bad; while in 11.5 per cent. the prognosis was good. I wish to emphasize the fact, however, that in the 11.5 per cent. of cases giving the diazo, the reaction was a weak one, promptly disappeared on treatment, and did not recur. Of 40 advanced stage cases in the white race, I got a diazo reaction in 24, or 60 per cent., 88.5 per cent. of which either died or grew worse. The 16 advanced cases which did not give a diazo, either improved or the disease was arrested.

From this observation, the logical deduction is that, in the white race, the presence of a persistent diazo reaction is of an unfavorable prognosis; while the absence of the diazo reaction in the white race is of a favorable prognosis.

Of my 100 cases, 27 were in the negro race. Of these, 15 were patients in an advanced stage, 8 of whom died, while 3 grew worse; the rest recovered or improved. There were five negro cases in the second stage, all of which either improved or recovered. There were 7 in the first stage of the disease, 5 of which took treatment, making an apparent recovery. Of the 2 not taking treatment, I have heard nothing further. In all of my negro cases, of all stages, never once have I found a diazo reaction. Those patients who died, lived from three days to ten months after I first saw them.

It is peculiarly striking that in as large a number of cases as 27, 15 of which were advanced

* Read at Medical Congress, 8th District, North Carolina, Winston-Salem, N. C., January 7, 1907.

stage cases, I should find an absence of the diazo reaction in every one. I have seen the diazo in the negro race in cases of typhoid fever, which goes to show that the diazo is a possibility in the blacks. It does, however, lead me to believe that possibly the chemical substance in the urine which produces a diazo reaction may be different in tuberculosis and typhoid fever. Also, that the chemical substance which produces the diazo in tuberculosis is not found in the urine of the negro suffering from this disease. This I frankly confess to be solely theoretical. It may be that, in the future, I shall find the diazo reaction present in the negro tuberculous urine, and that the cases which I have already observed are not sufficient in numbers to give accurate conclusions. It is strange to me, however, that out of 40 advanced cases in the white race, I should find a diazo present in 24, while in 15 advanced cases in the negro race, I should find it absent in every one of them. I feel that it is a point which is entitled to further and careful investigation.

My method of application of the diazo test is as follows: A specimen of urine, taken from the first passed in the morning, is selected. As soon as possible after its passage I make the test. If my first test is negative, I allow the urine to stand for twenty-four hours and again test it. I do this for the reason that on three different occasions, when associated with the Winyah Sanatorium at Asheville, N. C., I applied the test to specimens of urine which were still warm from the body heat, and failed to get a diazo reaction; yet, allowing the specimens to stand for twenty-four hours, testing again, in each instance I obtained a diazo reaction, which shows that a single test is not reliable.

The reagents which I use are three in number: Sulphanilic acid solution, sodium nitrite solution, and ammonia solution. To make the first, or sulphanilic acid solution, I dissolve crystallized sulphanilic acid in 5 per cent. hydrochloric acid to 1 per. cent. The second, or sodium nitrite solution, I make by disolving sodium nitrite in distilled water to 0.5 per cent. The third, or ammonia solution, is 10 per cent. aqua ammonia.

To apply the test, I put 5 c.c. of the sulphanilic solution in a test tube, to which I add from a pipet three drops of the sodium nitrite solution. This I thoroughly shake. I then add an equal volume of the urine to be examined and thoroughly mix. To this I add about 1 c.c. of the ammonia solution. If the diazo reaction is present, upon thoroughly shaking the foam will have a pink to a cherry-red color; and if allowed to stand for twenty-four hours, a dark green precipitate forms. The fluid will sometimes have a marked cherry-red color, yet the foam will be a pure white or a lemon-yellow color. This is not a diazo reaction. Occasionally, however, a specimen will give a white or yellow foam, and if allowed to stand for twenty-four hours, will give a greenish deposit. This is a diazo reaction.

It is therefore imperative, in order to determine the presence or absence of a diazo reaction, that we examine not only the fresh specimen, but also one which has stood for twenty-four hours. Also having made the test, we should allow the test tube, with the mixture in it, to stand for twenty-four hours, should we fail to get the coloration of the foam, so as to observe whether or no a greenish precipitate forms.

The conclusions which I deduct from these observations are:

(1) That for accuracy, should the fresh specimen fail to give the diazo reaction, we should allow the urine to stand for twenty-four hours and examine again.

(2) Having made the test, the foam failing to show the reaction, the mixture should be allowed to stand for twenty-four hours to see if there is or is not formed a greenish precipitate.

(3) That the absence of a diazo reaction in white tuberculous cases is of a favorable prognosis, as a rule.

(4) That the presence of a diazo reaction in white tubercular cases is of an unfavorable prognostic value.

(5) That the absence of the diazo reaction in the tuberculous negro is of no prognostic value.

(6) That there is possibly a racial difference between the whites and blacks which accounts for the absence of the diazo reaction in the urine of the tuberculous negro, and the presence of the diazo reaction in the urine of the white tuberculous in the advanced stage.

Intestinal Antisepsis in Fevers.—William F. Waugh declares that in every febrile disease, specific or otherwise, there is necessarily intestinal decomposition, toxin formation and absorption, and toxemia. He believes that about one-third of the fever and other symptoms may be credited to this cause, since the illness decreases in about this proportion after the bowels have been cleaned out and disinfected. The various symptoms are relieved to a much greater degree. These considerations apply to all fevers equally. When the deadly infectious nature of a typhoid stool is taken into account, it cannot be considered as a fit dressing for an ulcer. Cleanliness and asepsis are as desirable here as elsewhere. The writer expresses his preference in the choice of antiseptics for the use of the sulphocarbolates, following a complete emptying of the alimentary canal by doses of calomel, salines, and colonic flushings. These drugs are perfectly safe and never cause hemolysis or hematinuria. They are efficient and inexpensive. There is little taste when they are taken in hot water solution. When chemically pure, they are far more apt to settle an irritated stomach than to cause irritation. Toxic effects are not to be apprehended from overdosage.—*The American Journal of Clinical Medicine*

Alcoholism, Speed Mania, and Objectless Activities.—William Lee Howard discusses the effects of the hurry and unrest of modern life. Explosions of physical and psychical energy are continually taking place in the normal individual. They are disastrous or otherwise, according to their direction and the conditions coexistent with them. The writer believes that it is the study and supervision of these psychical explosions that will ultimately result in the thorough understanding and control of the effects of alcohol and those of its congeners, morphine and cocaine. He calls attention to the speed mania which so often attacks automobilists as one evidence of these increasing explosions of psychical energy. It is an objective symptom of the high nervous tension characteristic of the present day. He calls it a sociologic toxin. Relaxation, both mental and physical, is its antidota. That which is often called courage by the unthinking is in reality a psychic blindness to reason. Alcohol as well as the toxins of excitement can produce this. The writer believes that the automobile offers a wholesome vent for the reckless courage which otherwise would go to disorder and riotous excess.—*The Quarterly Journal of Inebriety.*

THE LOWERED BIRTH-RATE AMONG PROSPEROUS NATIONS.

A LOWERED birth-rate would seem to go *pari passu* with an increase of material prosperity and with a high degree of mental culture. France is the most conspicuous example of the truth of this proposition. On the whole, she is perhaps the most prosperous nation on earth, in that property there is divided upon a fairly equal basis. There are not such numbers of immensely rich individuals as in America and in Great Britain, but neither are there so many people in extreme poverty, in many instances verging on starvation, as there are in Great Britain. In a word, property is more equally divided in France than in any of the great countries of the world. As to mental culture, surely no race on earth can surpass the French. But the birth-rate of France is the lowest of any nation, nor is this a coincidence. America is now the richest country on the globe; her prosperity increases by leaps and bounds. Again, mental culture among all classes of native Americans has reached a very high standard. Indeed, native-born Americans are probably the best educated people on the face of the earth. Literature and science in America has made and is making great strides. But the birth-rate among native-born Americans has now for some years showed a steady and progressive decline. In place of the large families which used to distinguish Americans of native birth, one finds now families of two, and at the utmost three children.

Great Britain is very rich, and possesses a very highly-cultured section of its population, including many of the most brilliant representatives of literature and science in the world. The birth-rate of Great Britain, however, is falling lamentably, is exciting alarm, and giving rise to much discussion among thoughtful persons. With the exception of France, the birth-rate of Great Britain is the lowest of all the European countries. The annual report of the Registrar-General of England for 1905 has been issued recently, and a large portion of this report is given over to a consideration of the lowered fertility of English women and its effect on the birth-rate. According to the report, during the past thirty-five years the English birth-rate has fallen to the extent of 23 per cent. Basing the calculation on the proportion of births to possible mothers—women living at child-bearing ages—the decrease in the birth-rate for the period mentioned amounted to 29 per cent. In round numbers, 17 per cent. of this decline in the past thirty-five years is to be ascribed to the decrease in the proportion of married women of child-bearing age, and 10 per cent., perhaps, to the decrease of illegitimacy. The greater part of the remaining 73 per cent. of decrease is believed to be due to deliberate restriction of child-bearing by the people themselves. In 1876 the English birth-rate reached its high-water mark, 36.3 per 1,000 living; in the year 1905 it had dropped to 27.2 per cent.

With the advance of prosperity the birth-rate of Germany, although it still exceeds by far that of France and England, is nevertheless falling, and it is only more or less primitive countries like Russia that continue to add to their population at a rapid rate. Riches and sophisticated ways do not go hand in hand with increase of population.

As to whether it is well that races should increase and multiply freely is a point regarding which much may be said on either side. President Roosevelt is of the opinion that the larger the family the better it is for the country. This is very questionable, and especially in a country of limited area and with an overflowing population, like Great Britain, the subject for economic reasons at least is a debatable one, although, of course, restriction of child-bearing by artificial means is to be condemned.

THE FERMENTATION TEST FOR DRINKING WATER.

THE presence in water of ammonia, nitrates, and nitrites, together with considerable quantities of nitrogenous organic substances, indicates contamination with house drainage, and the simultaneous occurrence of large quantities of chlorine compounds indicates the presence of urine. Water cannot be regarded as sufficiently pure for drinking if it contains more than a trace of ammonia or more than 3 parts of chlorine, or 1.5 parts of nitric and nitrous acids in 100,000 parts. Serious epidemics, however, are occasionally produced by water which has successfully passed this chemical test and is also unobjectionable in taste and smell. This is due to the presence of pathogenic bacteria. Now, most specimens of water, like the air and the soil, contain bacteria in greater or smaller numbers. If a measured quantity of the suspected water is added to a mixture of bouillon and gelatin, and the mixture is allowed to congeal, each bacterium forms the nucleus of a colony which soon becomes large enough to be seen with the naked eye. Consequently, the number of organisms in the water can be determined by counting the colonies in the jelly. But this apparently simple method is open to several objections. It makes no distinction between harmless bacteria and disease germs, and, furthermore, the colonies grow slowly, occupying several days in becoming large enough to be counted. The gelatin culture method is suitable only for the regular and repeated examination of water of which the bacterial content is approximately known. A sudden large increase in the number of colonies then indicates a new contamination, but gives no information concerning its character.

Quite recently a new method has been introduced which is both simpler and more reliable. The impurities which render water dangerous to health are derived almost exclusively from human excretions,

and principally from feces, which appear to be the sole source of infection in cholera and dysentery, while urine also plays a part in the dissemination of typhoid fever. Now, all human feces contain immense numbers of *Bacillus coli*, while the germs of typhoid fever, cholera, and dysentery are present, if at all, in much smaller numbers. Hence it is easier to detect the *Bacillus coli* than the organisms above mentioned, and its detection is further facilitated by two properties which it possesses. It is one of the many microorganisms which cause sugar to ferment and evolve carbon dioxide, and it thrives when heated to a temperature which is fatal to most pathogenic organisms.

Surgeon-General Hammerschmidt, writing in *Die Umschau* of January 12, 1907, says that Eijkmann has utilized these properties of the *Bacillus coli* in the examination of water. The water, mixed with small quantities of glucose, peptone, and common salt, is placed in a J-shaped or barometer tube of glass and exposed to a temperature of 115° F. The short, open branch of the tube is provided with a bulbous expansion for the reception of the liquid forced by the gases of fermentation out of the long, closed branch, which at first is completely filled with the water under examination. The mouth of the short branch is stopped by a pledget of cotton wool to exclude dirt and atmospheric organisms. When water containing coli bacilli was subjected to this test, Eijkmann found that the liquid became turbid throughout, and there was more or less evidence of the formation of gas. With pure water, on the other hand, no gas is ever found, the only change being an occasional turbidity in the open branch of the tube after the experiment has continued forty-eight hours.

This simple test has been proved reliable by a long continued series of experiments. Unpolluted water taken from good city services, clean wells, springs, and woodland ponds, even very muddy water from marshy pools, if entirely free from human excretions, produced no fermentation, but river water at all contaminated with sewage fermented at once. The rapidity of the development of gas and turbidity depends upon the number of coli bacilli, but the test is so delicate that in several instances positive indications were obtained from pure water to which coli bacilli had been purposely added in a proportion as small as one bacillus in from 10 to 20 c.c.

SULPHUR IN THE TREATMENT OF MALARIA.

Although quinine must be acknowledged to be the most important factor in the treatment of malaria, it should by no means be regarded as the only one, for there are abundant proofs that, particularly in some of the chronic forms, the administration of quinine alone is altogether insufficient to accomplish the desired result. In a recent communication in the *Archiv für Schiffs- und Tropen-Hygiene*, Vol. X., No. 16, Diesing, who has had considerable personal experience with tropical diseases, calls attention to the value of sulphur as a prophylactic and curative measure in malarial infections. He found that among the natives of some of the South African countries, sulphur fumigations were commonly practised, the patient shutting himself or herself in a tightly closed hut and inhaling as long as possible the dioxide which resulted from the burning of the sulphur. In other instances the substance was given in the form of potassium sulphate dissolved in water. In the cases which he describes the fever disappeared within twenty-four hours, and a systematic examination of the blood showed the absence of the characteristic parasites. As the treatment indicated was combined with measures productive of extreme diaphoresis, Diesing was inclined to believe that the latter had an important bearing on the disappearance of the malaria, for it has often been observed that the natives could overcome the attacks by this means.

It is possible, however, to advance a very plausible theoretical explanation of the efficiency of sulphur preparations in malaria. It is well known that pigment constitutes an important factor in the development of the specific parasite, and is absorbed in large quantities from the red blood cells of the patient. The more firmly the hemoglobin is united to the red cells, however, the less the amount which can be taken up by the malarial organism. It has been found that sulphur, particularly when it is absorbed through the lungs in the form of sulphureted hydrogen or sulphur dioxide, unites with the hemoglobin to form sulphomethemoglobin. The latter is exceedingly stable, and it may be assumed that the resistance which it offers to the action of the oxygen of the air is similarly exerted against the disintegrating properties of the malarial parasites. We may then suppose that the development of generations of malarial organisms is interfered with because the necessary amount of the essential pigment is not at hand. The writer was so impressed by these facts that he employed a sulphur cure in his own case, and found that the parasites were promptly eradicated from the blood picture. Not only must these sulphur treatments be regarded as curative, but they also apparently possess a prophylactic value, for patients treated in this manner have been found to withstand the onslaughts of malaria on their return to the infected districts without a resort to quinine.

The observations noted are of extreme interest, and although not confirmed by the test of time or practice, ought to stimulate further research in this field. Sulphur baths, such as recommended by the author, are not difficult to obtain, and if they continue to meet with the good success in other hands which was achieved in the cases under Diesing's observation, the fact must be accounted a signal advance in the treatment of the dread malarial poisoning.

THE CAUSE OF DEATH IN ACUTE DISEASES OF THE PANCREAS.

Until a comparatively short time ago but little was known of acute pancreatic disease or the causes which lead to the rapidly fatal issue in many of the cases. Our knowledge of the subject is by no means complete, yet it has advanced sufficiently to permit of considerable progress in the treatment of the condition. In some experiments recently made, Guleke has found that by the production of an artificial embolus or the injection of various

fluids into the principal excretory duct of the pancreatic gland of an animal it is possible to produce a condition which in its clinical as well as pathological features closely resembles the acute hemorrhagic pancreatitis of the human subject. Guleke concludes, as the results of his experiments, that the pancreas itself as it undergoes necrosis in the body elaborates a toxic substance which is capable of causing death. It seems immaterial whether the pancreas of the experimental animal itself or one from another animal which has been introduced into the abdominal cavity undergoes necrosis, the result is the same. Guleke's observations therefore point to an acute intoxication from pancreatic necrosis as the cause of the fatal issue in these cases.

Further experiments have been made along these lines by v. Bergmann (*Zeitschrift für experimentelle Pathologie und Therapie*, Vol. 3, No. 2), who worked in conjunction with Guleke in an effort to determine the active agent which underlay this process. It was evident that the toxin developed in the normal as well as in the diseased pancreas and its secretions, but what seems most interesting is the fact that an almost perfect degree of immunity could be secured in dogs by the previous injection of trypsin in cases in which an artificial pancreatitis was produced or the gland from another animal had been implanted in the abdominal cavity. Acute pancreatitis seems to be a true autointoxication, and a more complete trial of the procedure indicated in this paper may lead to the adoption of some means by which the development of this fatal condition may be inhibited.

Retention of the Placenta.

It is generally considered good practice in the management of the third stage of labor to instruct the attending nurse or midwife to keep her hand pretty constantly on the fundus of the uterus, and to knead this vigorously if any relaxation of the organ takes place. This is done in order that concealed hemorrhage may not occur, and that any tendency to gaping of the uterine sinuses may be forestalled by the prompt induction of uterine contraction through the mechanical stimulation. Durlacher (*Münchener medizinische Wochenschrift*, February 19, 1907) expresses an opinion which is somewhat at variance with these rules. From an analysis of seventy-eight cases in which he has found it necessary in private practice to perform manual extraction of the placenta, he draws the conclusion that undue manipulation of the fundus is a very fruitful cause of imperfect separation of the placenta, and therefore of retention of the afterbirth. He ventures the opinion that the best prophylactic against retention of the placenta lies in not touching either the uterus or the abdominal walls after the birth of the child. This mode of procedure would involve such skillful observation of the patient's general condition, inspection of the abdomen, etc., as not to be feasible except in hospital practice, where plenty of highly trained assistance is available, and Durlacher therefore suggests that the following instructions be given to midwives: After the birth of the child the mother must be kept under constant careful observation. If it is not possible to perceive the position of the fundus by inspection of the abdomen, the hand should be gently applied to the abdominal wall and the position of the uterus determined. As the uterus alternately contracts and relaxes in the third stage as well as before, if the fundus should appear soft, in case there is no noteworthy hemorrhage, the hand should be kept quietly in position until the organ contracts again of its own accord. If the placenta has not been expelled at the expiration of an hour after the birth of the child, the position of the fundus should be ascertained as indicated. If it is below the umbilicus this is a sign that the afterbirth has not been detached and will probably not be spontaneously expelled, so that a physician should be called in. If, on the other hand, the fundus is above the umbilicus, the midwife may endeavor to express the placenta during a uterine contraction. If a hemorrhage of importance takes place the midwife should immediately have a physician summoned, and in the meanwhile should continue to massage and knead the fundus as long as the bleeding continues. We fancy, however, that a great deal of corroborative evidence of the value of such a mode of procedure will be necessary before obstetricians, as a class, abandon a doctrine whose practical application has so far seemed productive only of the best results.

Exophthalmic Goiter.

Great interest has been shown in the study of this subject by the medical profession for some years. Various theories have been propounded by different authorities and many treatises have been written to uphold these theories. Among the leading theories is that of Buschan, who believes that exophthalmic goiter is due to disturbed innervation. Other investigators believe that the seat of the disease is to be found in the medulla oblongata. Still others advocate the theory that this form of goiter is due to an affection of the sympathetic nerves. It has been said that this affection is a disease of the central nervous system, with a coexistent chronic intoxication. The theory embraced by Möbius is that exophthalmic goiter is due primarily to "hyperthyroidation," that is, to a disturbance of the function of the thyroid. This condition is directly opposed to the failure of thyroid function. Clinical evidence seems amply to support this theory. In the *Revue de Médecine*, December 10, 1906, Jean Lépine refers to the discussion of this subject at the Congrès des Aliénistes et Neurologistes, which met at Bordeaux in 1895. At this time two theories were proposed to explain the obscure pathogenesis of exophthalmic goitre. The first considered this disease a neurosis; the second considered it a disturbance of thyroid functions. The writer then discusses the methods tending to produce antithyroid immunity and describes his own personal investigations, as well as those of other authorities. Thyrotoxic serums prepared from the thyroid bodies of animals have been found to be comparatively inactive in relation to exophthalmic goiter in man. When, however, human glands were used, the experiments met with success. Lépine then refers to the report of Rogers, which was given to the New York Academy of Medicine on January 18, 1906. Various cytotoxins were prepared by Beebe for this work. The results of this first work showed that in a general manner these patients derived more advantage from the serum prepared from the diseased gland than from that prepared from the normal thyroid body. These authorities insisted upon the necessity of a long course of treatment. The writer believes that although serum therapy will probably be of aid in the treatment of Graves' disease, too much enthusiasm should be guarded against in relation to this method. In order to cure ex-

ophthalmic goiter it is necessary neither to suppress nor to restrain the thyroid function, but an effort ought to be made to do away with the effects which the reciprocal actions of vitiated secretions, both thyroid and others, have upon the nervous system. The vicious circle must be destroyed. It may be useful in this attempt to combat the general state of intoxication by specific antitoxins. This is the rôle of serum therapy.

Hydatid Cysts of the Kidney and of the Spleen.

It has been learned from the compilation of statistics that the genitourinary system ranks second as the seat of hydatid disease, although in comparison with the liver this location is rare. In some cases the kidney is converted into a huge cyst which resembles hydronephrosis. In an interesting article on hydatid cyst of the spleen in the *Gazette des Hôpitaux*, October 27, 1906, André Martin declares that the beginning of a hydatid cyst of the spleen may present variable symptoms. Often at the beginning the evolution is insidious and the swelling is recognized only by chance. In other cases pain develops months or years before the appearance of the cyst; in still other patients there exists a profound anemia, the cause of which cannot be determined, while at more or less regular intervals painful crises in the epigastrium and the left hypochrondrium occur. An important symptom is cardiac pain and especially the impossibility of the patient to assume the left lateral decubitus. Osler says that a diagnosis of hydatid cyst of the kidney is possible only by puncture and by examination of the fluid. The cyst sometimes perforates into the pelvis of the kidney and parts of the cyst may be discharged with the urine, giving rise to renal colic. A case is reported in which the patient for many months passed at intervals numbers of small cysts in the urine. Nevertheless the general health was hardly disturbed, aside from the attacks of colic, which occurred while the parasites were being voided. In the cyst of the spleen of the type of ascending evolution a differential diagnosis must be made from affections of the pleura and the lungs. In the case of cysts with descending evolution mesenteric cysts must be eliminated. The symptoms are the same, constipation, vomiting, dyspeptic disturbances; but the tumor of the mesentery is medium, while the splenic tumor is a little to the left. In the cyst of the spleen of posterior evolution especial care must be made to differentiate this from affections of the kidney with which it can easily be confused. In the cyst of the spleen with anterior evolution the diagnosis appears to be more easy. As to the treatment of echinococcus disease medicines are of no benefit. Martin declares that the most simple method of treatment is puncture, but this is not exempt from danger. Splenectomy when the spleen is affected assures rapid and radical cure.

The Dermatological Congress in New York.

As we have previously noted, the Sixth International Dermatological Congress will be held in this city, September 9 to 14 of this year. The program arranged is an attractive one, and it is expecially noteworthy that the subjects chosen for general discussion are not of exclusive dermatological interest, but appeal to the general practitioner as well. The first theme, "The Etiological Relationship of Organisms Found in the Skin in Exanthemata," gives promise, not only of able presentation, but also of keen critical discussion, while the advantage to be derived from acquiring a scientific basis for quarantine and prophylaxis in these diseases is so great that this investigation must interest everyone concerned in the problems of hygiene and public health. The second theme, "Tropical Diseases of the Skin," while not of so much general importance, still is particularly apposite now that our attention is so frequently turned to the medical conditions of lands near the equator, and that we are apt to encounter tropical diseases or their sequelæ in the persons of those returning from our island possessions. The third theme, "The Possibility of Immunization Against Syphilis" and "The Present State of Our Knowledge of the Parasitology of Syphilis," takes up a subject in which until three years ago all advance seemed blocked by the impossibility of experiment, due to the lack of a susceptible animal. Metchnikoff's demonstration that the chimpanzee, when inoculated with human virus, will develop not only a chancre but also, as a rule, typical secondary lesions on the skin and mucous membranes, was the starting point of hundreds of animal inoculations which have revolutionized our knowledge of this disease, and whose significance is as yet not fully appreciated. Whatever our interpretation of the presence of the *Spirochæta pallida*—and the conviction that it is indeed the long-sought causative organism is steadily gaining ground—the investigations of the last three years have solved many long-debated problems, and give promise of yet greater advances in the near future.

The Treatment of Varicose Veins.

Nearly half a century ago Desgranges employed for the treatment of varicose veins a method that had been suggested by Pravaz for use in cases of aneurysm. It consisted in causing thrombosis in the vessels in question by the injection of a few drops of concentrated solution of ferric chloride. Although Desgranges is said to have had a certain amount of success with the method, its disadvantages are so obvious that it is not astonishing that it never became popular. Trendelenburg's operation of ligating the saphenous vein high up was founded on correct principles, and has been widely used, giving according to Tavel (*Berliner klinische Wochenschrift*, February 18, 1907) about 75 per cent. of permanent cures. This author has attempted, by means of a combination of the old idea of Pravaz and Desgranges with that of Trendelenburg, to obtain better results, and states that he has now applied his procedure with success in twenty-seven cases. Briefly stated, the operation is performed as follows: With the patient standing, so as to cause the veins to become prominent, the varicosities and the course of the saphenous vein are indicated on the skin by means of fuchsin. The saphenous vein is then ligated in the upper portion of its length, and preferably a short section is excised in order to avoid any possibility of regeneration. The next day the process of inducing thrombosis in the varicosities is begun by injecting into the dilated vessels small amounts of 5 per cent. carbolic acid solution. This effects a local reaction of the vessel wall, which leads to thrombosis, and the injections are repeated at intervals of a few days until the entire area has become thrombosed. Ultimately the thrombi become organized and the veins are converted into fibrous cords. The treatment is somewhat painful, is often accompanied by elevations of temperature, and more or less time must usually be spent in bed, so that its advantages seem rather questionable.

News of the Week.

Offensiveness of Dictatorial Methods in Editing Official Journals.—Since "every rose has its thorn," it should not be overlooked at this time that the flowery probabilities of mutual scientific medical journalism might easily be inhibited, and even destroyed, by the thorny possibilities of selfish time-serving desires. In any event, common justice demands that all questions of mutual material interest, and others of general interest to the profession of the State, should find free and impartial utterance through the pages of its own journal. The presence of a spirit which contemplates that the entire membership of the profession of this State be not made familiar by its own servants with the facts relating to the respective differences in all matters of common importance is offensive to the principles of American institutions, and to those of fair dealing in all lines of manly action.—From the presidential address before the Medical Society of the State of New York by Dr. Joseph D. Bryant, President-elect of the American Medical Association.

Ray Brook Tuberculosis Sanatorium.—The Board of Trustees of the New York State Hospital for Incipient Tuberculosis at Ray Brook makes an appeal to physicians for greater efforts to recognize cases of pulmonary tuberculosis in its earliest stages, and states that the institution still suffers under the difficulty of securing patients whose lesions are slight. In the hospital there are now over thirty vacant beds, and this is said to be due to the fact that suitable cases for treatment, and for which the hospital was built, cannot be secured. Out of 940 applications for admission to the hospital last year, 220 patients were, following examination, received for treatment, the remaining 720 being too far advanced to be accepted. Of the 220 received, 65 per cent. only were actually incipient cases; the balance on admission were found to be suffering from more advanced disease, and were reclassified at the hospital. In the last annual report of this hospital it is shown that 85 per cent. of incipient cases were discharged apparently recovered. This class constituted 65 per cent. of all cases under treatment. Of the moderately advanced cases 23 per cent. were discharged apparently recovered, and of the advanced cases none were so discharged. The possibility of obtaining good results is plainly seen, therefore, to depend in the main upon the amount of tuberculosis present when the patient is placed under treatment. The definition of an incipient case, as adopted by the National Society for the Study and Prevention of Tuberculosis, is as follows: "Slight initial lesion in the form of infiltration limited to the apex or a small part of one lobe; no tuberculous complications; slight or no constitutional symptoms (particularly including gastric or intestinal disturbance or rapid loss of weight); slight or no elevation of temperature or acceleration of pulse at any time during the twenty-four hours, especially after rest; expectoration usually small in amount or absent; tubercle bacilli may be present or absent." It is desired to receive patients of this type to the full capacity of the Ray Brook institution.

The Milk Question.—At a meeting of the members of the Department of Health held last week resolutions were adopted requiring farmers and others producing and handling milk to exercise greater care than has been the case in the past to prevent contact with the dairy products by persons suffering from infectious diseases. One resolution provides that after April 1 every creamery or milk station which ships milk or cream, or both to the city of New York, shall be required through its agents to furnish to the Department of Health on Monday of each week a report stating the existence or nonexistence of either typhoid fever, tuberculosis, diphtheria, scarlet fever, dysentery, or any other infectious disease in the households of all persons employed in the collection or handling of milk, either at the creamery or at the farms or dairies supplying it. Another resolution requires the farmers and dairymen to make similar reports to the creameries every Saturday. Such reports are to be kept on file in the creameries for six months, and shall be open at all times to the inspection of the Health Board. Should one of these diseases break out in the family of any employee the latter shall be excluded from duty in connection with the handling of milk until a physician certifies that there is no longer danger of carrying the infection. Another resolution regulates the use of water in cleaning milking utensils near a place where typhoid fever or dysentery is known to exist. Failure to comply with these requirements may be sufficient to exclude milk or cream from the offending milk stations or creameries. It will no doubt be easy to induce the persons interested to make out these reports and hand them in, but the reliability of the data furnished in this way can hardly be above suspicion.

A Question of Proprietorship.—Whether the spoils of an operation belong to the victor or the victim is a question that comes up perennially. A recent instance is attracting interest in Germany, in which a patient, relieved of a bladder stone, has refused to pay the surgeon's bill unless the calculus is handed over to him. The stone is being retained by the operator, because it has especial interest, as its nucleus consists of a broken-off catheter tip. It is expected that the matter will go into the courts. No doubt it would be better to make a stipulation in regard to the disposal of such trophies before the operation, as patients would be more likely to be willing to resign all claim to objects of this sort before their removal than afterwards.

The Medical Society of the County of Westchester had its annual dinner at the Hotel Astor on March 19. The society dates from 1797, and claims to be the oldest organization of the kind in the United States. Dr. H. Beattie Brown of Yonkers presided. Dr. E. M. Hermance of Yonkers read a paper on "Pelvic Inflammation" and a discussion by the members followed. There were 123 members present.

Antitoxin from Convicts.—At a recent meeting of the Baltimore County Medical Association, Dr. H. Burton Stevenson said that antitoxins would be more effective if they were prepared in the human body, because only a few animals are susceptible to the diseases of man. He suggested that such antitoxin could readily be produced by using criminals for the production of serums. A law could be enacted making the punishment for certain crimes optional with the convict, imprisonment on the one hand, inoculation with certain disease germs on the other.

A Bill to Prevent Procreation of Certain Criminals.—A bill now before the Indiana Senate provides for the sterilization of confirmed criminals, idiots, imbeciles, and those guilty of the crime of rape. The bill has already been passed by the House. According to the bill, each institution in

the State intrusted with the care of confirmed criminals, idiots, rapists, and imbeciles, is to appoint upon its staff two surgeons, whose duty it shall be, in conjunction with the chief physician of the institution, to examine the mental and physical condition of such inmates as are recommended by the institutional physician and board of managers. If, in the judgment of this committee of experts and the board of managers, procreation is inadvisable, and there is no probability of improvement of the mental condition of the inmate, it shall be lawful for the surgeons to perform such operation for the prevention of procreation, as shall be decided safest and most effective. It is established that the consultation fee to the experts shall not exceed three dollars in any one case.

Health Defence League Incorporated.—The Public Health Defence League of New York City was incorporated at Albany on March 15. The directors include Austen G. Fox, Ernst J. Lederle, Thomas R. Slicer, and Thomas Darlington of New York, Howard J. Rogers of Albany, Robert E. Belcher of Boston, and Henry W. Cattell of Philadelphia. The organization has for its objects to work against practices and conditions of every kind that are dangerous to the public health and morals and to assist in the enforcement of laws against quackery and charlatanism, and the prevention of adulteration of drugs and food substances, and the sale of narcotics, alcohol, and dangerous substances.

Food-Testing Laboratory for Boston.—At a meeting of the executive committee of the Carnegie Institution held in Washington, D. C., on March 11, it was decided to establish in Boston, Mass., a laboratory for the purpose of conducting experiments in nutrition. An appropriation of $100,000 was allotted for the erection of a building, and the balance is to be devoted to the scientific investigations of the nutritive value of various foodstuffs during the present year. Prof. F. G. Benedict of Wesleyan University was selected as director of the new laboratory.

Women Medical Students in Germany.—According to the *Münchener medizinische Wochenschrift* there are at present in the seven universities of Freiburg, Heidelberg, Tübingen, Munich, Erlangen, Würzburg, and Leipzig, which admit women, 254 female students, a notable increase over previous years. Of these, 116 are studying medicine, 92 philosophy, history, and languages, 28 mathematics and natural sciences, and the remainder are dispersed among various other subjects. Medicine is losing in popularity, and philosophy, languages, and history are gaining more adherents.

Medical Fees in Germany.—Following the example of the physicians of Berlin and Vienna, the members of the Wiesbaden branch of Leipziger Verband have decided to announce to the public an increase of 25 per cent. in medical fees, the change to take effect from January 1, 1907. A minimum has been established of two marks for a visit and one and a half marks for an office consultation.

The New German Reichstag, like its predecessor, has among its members eight physicians.

Christian Science in Delaware.—The Delaware Senate has passed a bill opposed to the practice of Christian Science and faith treatment in that State. The bill had passed the House two weeks before, and, after a final open debate between representatives of Christian Science and the medical profession, was passed by the Senate by an overwhelming vote.

Naturopath Held for Trial.—A self-termed "naturopath" was brought before the Yorkville Court last week charged with practising medicine without a license. An agent of the County Medical Society testified that he had prescribed a dietary régime and hot-air baths for a stiff neck which she consulted him about, and had charged her two dollars for the advice. He was held in $500 bail for trial, as was also a Second avenue druggist, who was accused of prescribing.

Osteopathy Bill.—The Assembly Committee on Public Health has reported a compromise Osteopathy bill which provides that all osteopaths now in the State who are graduates of some osteopathic school are to be recognized by the State, but in future osteopaths must conform to certain regulations concerning their medical education.

Health Statistics in Montreal.—A report just issued by the Health Department of Montreal shows that the death rate of Montreal is larger than that of any other important city of the continent. The rate during the last year was just a fraction less than 22 per 1,000, an increase of 2 per cent. over 1905. At the same time the birth rate is shown to be the highest of any large city on the continent.

New Journals.—A new journal devoted to the subjects of orthopedics, medical gymnastics, and massage appears under the title of *Zentralblatt für Chirurgische und mechanische Orthopädie*. It is a monthly, and is published in Berlin under the editorship of Prof. O. Vulpius of Heidelberg, together with a long list of co-editors comprising many of the best known European orthopedists. Like the other so-called *Zentralblätter*, it consists of several short original articles and a large number of abstracts of the literature relating to the subjects in question. The *British Journal of Tuberculosis* is a quarterly publication of which the first number has been issued. It is published in London and is edited by Dr. T. N. Kelynack.

Journals Consolidated.—The proprietors of the *Medical Era* have acquired the *Medical Mirror*, and in future the combined journals will be issued under the name of the *Medical Era*. The April issue of the *Medical Era* will be the first number of the consolidated journals. The editors will remain as before, Drs. S. C. Martin and Clarence Martin.

Brooklyn Home for Aged Men.—An endowment of over $150,000 has been made to the annex of the Brooklyn Home for Aged Men in Classon avenue and Park place by Mrs. Edward S. Harkness in memory of her father, Thomas E. Stillman, who died in September last. The annex was erected three years ago by Mr. Stillman in memory of his wife, and is known as the Elizabeth Greenman-Stillman Memorial.

Legacy for Yale Medical School.—By the will of the late Gen. Samuel E. Marwin, which has been filed in the Probate Court, $5,000 is set aside for the Yale Medical School and $25,000 for the New Haven Hospital.

Katonah Typhoid Cases.—A report made by Dr. D. D. Jackson, chief chemist of the Water Department of this city, states that the water supply from the Croton watershed shows no evidence of contamination by the recent cases of typhoid fever occurring in Katonah.

The Webster County (Mo.) Medical Society was organized in Marshfield on February 27 by Dr. T. A. Coffelt of Springfield district, councillor for the twenty-fifth district. The following officers were elected: *President*, Dr. M. Highfiell, Marshfield; *Vice-President*, Dr. J. A. Rabenau, Fordland; *Secretary*, Dr. W. R. Beatie, Rogersville; *Treasurer*, Dr. E. M. Bailey, Elkland; *Censors*, Dr. D. A. Will-

iams, Niangua; Drs. W. H. Ballinger and Eli Trimble, Seymour.

Ontagamie County (Wis.) Medical Society.—At the annual meeting of this society held in Appleton on March 6, officers were elected as follows: *President,* Dr. W. N. Nolan, Kaukauna; *Vice-President,* Dr. H. W. Abraham, Appleton; *Secretary and Treasurer,* Dr. M. J. Sandborn, Appleton.

Obituary Notes.—Dr. Edward W. McDonald of Waterbury, Conn., died suddenly of heart failure on March 13, at the age of sixty-seven years. He was born in Limerick, Ireland, but was educated in this country, and received his degree from the University Medical School. He had practised in Waterbury nearly forty years.

Dr. William Lame, a retired physician living in this city, died suddenly on March 13 at the age of seventy-four years. He had practised in St. Catharines, Ont., in Lockport, N. Y., and in Swarthmore, Pa.

Dr. Oronhyatekha of Toronto, Can., died on March 3 in Savannah, Ga., of heart disease and diabetes. He was a fullblooded Mohawk, and was born on the Six Nations reservation near Brantford, Ont., in 1841. He received his medical education in Toronto University and also at Oxford, Eng. He commenced practice in Frankford, Ont., but in 1875 removed to London, Ont., where he remained until 1889, when he took up his residence in Toronto.

Dr. Henry Clay Smith of Kent, Wash., died on March 2, at the age of fifty years. He received his medical degree from the University of Ann Arbor in 1883, and had practised in Portland, Tacoma, and Kent.

Dr. Joseph C. B. Ray of Denver died of pneumonia on March 5, at the age of fifty-one years. He was a native of Kentucky, and for fifteen years practised in Owensboro in that State. He had been a resident of Denver for about six years.

Dr. J. E. Lothrop of Dover, N. H., died of heart disease on March 6. He was born in 1826 in Rochester, and received his medical education in Jefferson Medical College. He was prominent in public affairs and was twice Mayor of Dover.

Dr. Charles M. Fenn of San Diego, Cal., the oldest physician in the city, died on March 7 of nephritis. He was born in Hamilton, O., in 1835, and was graduated from the medical school of the University of California in 1865. He practised for three years in San Francisco and then removed to San Diego. He had held many official positions in San Diego, and for a number of years was Army post surgeon.

Dr. Columbus Hixon of Kansas City, Mo., died on March 7, at the age of eighty years. He was one of the founders of the Kansas City Medical College, and was said to have been the first surgeon in that part of the country to perform a successful cataract extraction.

Mr. James R. Lathrop, for over twenty-three years superintendent of Roosevelt Hospital, died of apoplexy at that institution on March 13. He was born in Poughkeepsie in 1847, and, after serving in the Civil War for two years, he was made chief clerk in the Lincoln General Hospital at Washington. For several years he was in mercantile life, and finally became supervisor at the Bloomingdale Asylum in New York. In September, 1883, he assumed charge of the Roosevelt Hospital, where he had since remained. On account of failing health, he tendered his resignation, to take effect March 1. Mr. Lathrop's executive ability, sterling character, and gracious manner gained for the institution and for himself many friends.

THE TENTH HARVEY SOCIETY LECTURE.

The last lecture of the present series given under the auspices of the Harvey Society was delivered at the Academy of Medicine on Saturday, March 9, in the presence of a large audience. The speaker was Prof. Friedrich Müller of Munich, Germany, and the topic was "Some Neuroses of the Heart." In introducing the speaker, the chairman, Prof. Graham Lusk described the Friedrich Müller Clinic as really typifying the clinic of modern Germany. It consisted of a hospital with 220 beds, looked after by two resident physicians who had been with Prof. Müller for over five years. The clinic also embraced physiological, chemical, and pathological laboratories with the necessary workers. The results of the laboratory were at once applicable to the clinical treatment of the patient, and the whole was coordinated as probably in no other clinic in the world. In opening his lecture, Prof. Müller stated that he believed that observations at the bedside were just as scientific as those of the experimental laboratory. In the study of the heart, however, we had been slow to apply experimental methods; we were only beginning to avail ourselves of experimental pathology in this field.

The speaker then discussed the heart in its physiological aspects. It was only part of the circulatory system, and in the closest relation with the other parts. As was well known, the heart of many animals could be cut out and would continue to beat for some time. This showed, of course, that the nerves to the heart did not originate the movements; they merely controlled them. The blood was not only a lubricant to the heart, but also a stimulus. Ringer's solution had the same effect, and the experiments of Howell had shown it was mainly the calcium ions to which the stimulation was due. Prof. Müller then described in detail the innervation of the heart and the other elements that played an important rôle in the action of the organ. Among the latter was the bundle of His, a structure only recently adequately studied. It consisted of peculiarly-shaped muscle cells described by Purkinje, and lay mostly in the interventricular septum. A considerable part of the bundle was broken up and distributed in the tissues of the apex. It had been found that permanent injury to the bundle led to an irregularity of the heart's action, so that the ventricular contraction no longer followed regularly on that of the auricles. This was met with in a number of clinical conditions, permanent bradycardia among others, and these were, therefore, no longer to be regarded as neuroses of the heart. He outlined the origin and distribution of the vagus and described its two sets of fibers, and also discussed the functions of the sympathetic innervation. The former was probably the more important clinically. It reduced the work of the heart to that degree which was sufficient for the body tissues at that particular time. In considering the innervation of the heart, one had also to bear in mind the vasomotor dilator and constrictor nerves, which were really a part of the cardiac mechanism. The entire regulatory mechanism was of paramount importance, since it responded to all kinds of stimuli.

The speaker then passed on to the subject proper, the various so-called neuroses of the heart. We had come back to believe that there was such a condition as nervousness, though now we called it neurasthenia. In individuals suffering from this condition, there was a low vitality of the mind and of the cerebral centers. The centers were often highly irritable, so that a slight stimulus, instead of remaining more or less confined to one center as it would do

in a normal individual, spread its effects over a wide area of nerve tissue. The symptoms usually associated by clinicians with this condition were alterations in the pulse rate, in its rhythm, palpitation of the heart, fluctuations in blood pressure.

Taking up these various points, Prof. Müller said that alteration of the pulse rate was one of the most common cardiac changes associated with nervousness. The rate of the pulse was often increased, but the increase was seldom permanent. In neurasthenia periods of regular pulse alternated with those of rapid or of slow pulse. If the increased rate were permanent, other lesions should be thought of. With excessive muscular work, as for example in hill climbing, if the condition were due to neurasthenia there would be no dyspnea. If dyspnea were present, or if there were evidences of a defective circulation one should not diagnose a "nervous heart."

Arythmia was seen in nervous heart, but it was not a common condition. There was the so-called "changing pulse," in which only the duration of the diastole was concerned. This was really an exaggerated reflex by way of the vagus. The "pulsus alternans" was never a symptom of nervous heart; it was always associated with some myocardial lesion. Extra systoles constituted one of the most frequent of pulse irregularities. Did this too occur in nervous heart? Prof. Müller thought it did not. This irregularity was always encountered when the amount of work to be done was out of proportion to the heart muscle. So, if there was any damage to the heart muscle one would always find a marked increase in the extra systoles. Perhaps occasionally, with only a little extra systolic irregularity, there was no diseased myocardium, but on the whole this symptom indicated a lesion which would show itself in other ways perhaps several years later.

In discussing palpitation of the heart, the speaker warned against confounding it with high frequency. In true palpitation the shock with the beats was so forcible that the patient should be able to count them without holding the hand to the heart. The physician should control the counts by noting the pulse. Tracings of the apex were apt to throw some light on the cause of the palpitation. In nervous heart the curve rose very suddenly, whereas in the normal heart the ascent on the tracing was more gradual. This would indicate that in the former the systolic contraction reached its maximum very quickly. The first sound in this condition in nervous heart was louder and more accentuated. If the muscles contracted very slowly, as for instance in aortic stenosis, one would miss the first sound entirely. Radial sphygmographic, manometric tracings were also of considerable value in these conditions. The speaker illustrated this by tracings of two kinds of cases.

The blood pressure normally varied within very narrow limits. In nervous heart, on the other hand, there was a liability to great fluctuations. Clinically, the cases then showed liability to flushings of the head, to attacks of fainting, migraine, sudden perspiration, cold hands and feet. The palpating finger could often appreciate the changes in the blood pressure. If the pressure stood permanently high, one would not go wrong in diagnosing a beginning arteriosclerosis. In nervous heart the size of the organ showed no change, although perhaps in cases of long standing there would occasionally be found an enlargement, but this was not at all common.

Feelings as of impending death and painful sensations about the heart were often noted. Occasionally these had their origin in the thoracic wall rather than in the heart. Attacks of angina pectoris, or rather something like that condition, were sometimes encountered. In nervous heart, however, the pain was not really severe. Prof. Müller, in fact, doubted whether pseudoangina pectoris really occurred in nervous heart. If angina pectoris occurred there was probably a real lesion, such as coronary arteritis.

There were a number of cardiac affections formerly regarded as of nervous origin which now were known not to be such. An example of this was the heart in goiter. In Southern Germany many cases of supposed nervous heart were really cases of incomplete hyperthyroidism. Such a heart could be distinguished from the true nervous heart by the fact that the increase in the heart rate was permanent, and the acceleration in general was not as high as in nervous heart. It might be 120 to 140 per minute, whereas the nervous heart often had much faster periods. The presence of tremors, the loss of flesh, a slight soft swelling of the thyroid, these all helped in the diagnosis. The administration of even small doses of thyroidin often established the diagnosis, for it made the hyperthyroid heart worse.

The excessive use of coffee, tea, or tobacco also gave symptoms that simulated a nervous heart. The speaker said tobacco and not nicotine advisedly—for recent work had shown that the nicotine was not the factor involved. Tobacco produced a distinct increase in blood pressure in nervous hearts; sometimes it caused symptoms of a pseudoanginal character. Alcoholic drinks also produced the symptoms of a nervous heart. The worst form was beer. In women and young people even small quantities often produced marked disturbances.

Injured and feeble hearts, such as were met with after acute infectious diseases, also simulated a nervous heart. The poisons of the tubercle bacilli could bring about a similar condition. The cardiac disturbances associated with affections of the sexual organs, *e.g.* arythmia in pregnancy or in disease of the ovaries or uterus, were not referable to a nervous heart. They were more or less obscure intoxications.

Finally, the speaker alluded briefly to paroxysmal tachycardia, a condition often setting in suddenly with a heart rate of 140 to 160, and, after lasting several days, as suddenly ceasing. This would sometimes be found to be closely related to migraine or occasionally to epilepsy. The more thoroughly a physician examined his case, the less often would he make the diagnosis "nervous heart." It should only be made after everything else had been excluded.

Therapeutically, the nervous heart should be treated by attention to the general health of the patient, removing him from overwork, excitement, and worry. A change of environment was excellent. These patients did well in high altitudes. The crowded places, especially the various baths, should be avoided. Above all, no medication directed to the heart should be given.

The Death of Professor Berthelot.—The eminent French chemist, Pierre Eugène Marcellin Berthelot, died suddenly on March 18, at the age of eighty years. He was watching at the bedside of his dying wife, and when told that her life was extinct he rose from his chair, threw up his arms, and fell dead. He had been professor of chemistry at the Collège de France since 1865. He was a member of the Institute and in 1889 was made perpetual secretary of the Academy of Sciences. Among his notable discoveries were smokeless powder and acetylene gas.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

KALA-AZAR—CEREBRAL TUMORS—THE PARATHYROIDS—GYNECOLOGY NOW AND FIFTY YEARS AGO—PROPOSED MEMORIAL—HOSPITAL MEETINGS—THE EPIDEMIC.

LONDON, March 1, 1907.

THE Milroy Lectures this year have been entrusted to Dr. Leonard Rogers, Professor of Patholo— Calcutta, and those interested in tropical discourses will be pleased that he has devoted them to kala-azar, which has spread slowly for the last thirty years up the Assam Valley. The disease is endemic in some districts of India and in its epidemic form seems to be identical with Burdwan fever, and sporadic cases seem to be just the same as the "malarial cachexia," so well known to Indian medical officers and characterized by persistent fever, of an alternating remittent and intermittent type, often mistaken for typhoid, but rapidly leading to a cachectic condition, with great enlargement of the spleen and later of the liver, and extreme wasting. The fever may last months or years. The mortality is from 98 per cent. at the height of an epidemic to 75 per cent. towards the end. The cause is almost certainly a protozoal parasite discovered and described by Leishman and Donovan and which has been said to be one stage of a flagellated parasite, and there are good reasons for thinking that a biting insect is the carrier of the infection. Dr. Rogers dealt in his first lecture with the epidemiological aspect of the disease. Public attention was first attracted to kala-azar in 1882 when Dr. Clarke's report contained notes on 120 cases. It had, however, been known from 1871 to 1876, and Dr. Rogers gave full details of its spread in Assam with a map, charts, and diagrams. The lecturer was selected in 1896 to investigate the disease, and after a year's study came to the conclusion that it was an intense form of malarial fever, an opinion endorsed by Ronald Ross after a personal investigation in 1899. Earlier views, such as attributed the disease to ankylostomias or to epidemic Malta fever, are therefore superseded. Burdwan fever, mentioned above, named after a district it affected in Bengal, must, it seems, be considered the same as kala-azar, of which Dr. Rogers has lately found the parasites in some sporadic cases from Burdwan. Another epidemic in 1808 of the same nature was called kala-dukh. In 1904 Dr. Rogers on visiting the district where it had prevailed found a few chronic cases remaining, and also a number of sporadic cases. In some of these he discovered the kala-azar parasite, so the identity with kala-azar may be regarded as established.

In his second lecture Dr. Rogers described the disease itself—its course, complications, and terminations. He showed that it was not one whit less terrible when considered individually than collectively, as it killed by inches after most prolonged sufferings which we were powerless to effectually check. He showed a number of lantern slides of groups of cases and pointed out their salient features, the most marked perhaps being the tumid bellies, due to enlargement of the spleen and sometimes also the liver, in striking contrast with the wasted face, chest, and limbs. Some slides showed the frequency of cases in children, the incidence decreasing in later decades; others the extreme wasting in the last stages and the dropsical and ascitic form produced by a peculiar intracellular cirrhosis of the liver. The incidence in family, age, sex, race, season having been considered, the type of fever, the blood changes, condition of liver and spleen, and complications were carefully dealt with. Then came treatment, and on this the lecturer emphasized his well known method with massive doses of quinine. If it will not cure, it will often delay the progress so much as to make the patient comfortable for long periods. In view of occasional recoveries from hopeless conditions, Dr. Rogers hopes for the discovery of a better remedy, but in the meantime he gives quinine in massive doses—60 or even 90 grains a day, and says these amounts may be persisted in for months together. The good effect of such doses was shown by a nine months' chart of a child of eight who took 50 grains a day for seven weeks, her weight steadily rising all the time and no ill effect being produced.

In the second Lettsomian lecture Dr. C. E. Beever proceeded to describe six cases of tumor involving the second or middle frontal convolution. In them all there were attacks varying according to the precise position of the tumor. In all the mental condition was dull, slow, or inattentive, and the memory bad, but in none were the sphincters affected. Sensation was not affected or slight anesthesia to slight touch was only temporary and after the fits. In four out of the six fine tremor of the fingers on the same side as the tumor was detected. It appeared then that fits, faints, or attacks beginning with spasms of conjugate movement of the eyes, or of the hand or face, followed by weakness but not permanent anesthesia, mental dullness and fine tremor on the side opposite to the one affected by the fits, indicated tumor of the outer surface of the frontal lobe anterior to the ascending convolution. Dr. Beevor then related cases in the interior of the lobe, the difficulties of their diagnosis being pointed out, especially before hemiplegia appeared from extension of the growth backwards. Severe headache, vomiting, double optic neuritis, mental obtuseness, incontinence of urine, gradual hemiplegia without anesthesia, increase of deep reflexes with decrease of superficial ones, and extensive plantar responses on the paralyzed side were the chief indications. In three of the cases there was rapid, fine tremor of the hand on the same side as the tumor, and this was the most significant symptom.

The Pathological Society had two papers before it on the 10th concerning the parathyroid glands. The first, by Dr. David Forsyth, dealt with their anatomy. Usually he found two on each side, but the total might reach twelve. They never lay on the superficial aspect of the muscles, and might occur within the thyroid itself. The microscope was necessary to identify them. With their tissue might be bound up thymus or accessory thyroidal. In infancy they were smaller but greater in number, while accessory thyroids were more numerous in adults, suggesting that one might be transformed into the other. The colloid in parathyroids and thyroids seemed the same and was oxyphile as a rule. In infancy the cells were in a resting stage and colloid appeared later.

The second paper was by Mr. W. L. Harnett, who described the appearances in various periods of life and thought that the tissue began activity early, increased as age advanced, and attained its height late in life. From examinations of subjects dead from various diseases he found nothing different from normal glands at the corresponding age. There were no grounds for supposing parathyroids were affected in Graves's disease or in tetany. Dr. H. Bayon did not believe that colloid was formed in true parathyroid tissue; if seen it would only be an isolated lobule of the thyroid proper. He exhibited a section through a goiter showing the parathyroid in which was no trace of colloid.

The new President of the Gynecological Society is Mr. W. D. Spanton, Consulting Surgeon to the North Staffordshire Infirmary. He delivered his address on February 14, devoting it to the gynecology of to-day and fifty years ago. Having referred to the opposition at first to ovariotomy and to the radical cure for hernia offered by London teachers whose knowledge of anatomy and surgery should have prevented their attitude, he went on to consider their position in reference to affections of women. His first example was excision of the cervix uteri for various forms of cancer which was condemned by Churchill, Montgomery, and Robert Lee. But Simpson had then operated on eight cases and only one died. It was not to be wondered at that the operation was regarded as so grave considering the mode of its performance then. It was only when the true principles of clean surgery were adopted that real success was attained, and no one now expects a fatal result from this operation. Extirpation of the whole uterus at that date was even more rigorously proscribed. The immediate results are now less grave, though how far it is curative for malignant disease is an open question. Vaginal hysterectomy had been practised for prolapsus associated with various conditions, but removal of the organ when *in situ* for tumors had only just begun. Of nineteen cases sixteen had died, only one surviving to the fourteenth day. This fatality was so alarming that Clay of Manchester and Köberle of Strasburg ventured on abdominal hysterectomy. Dr. Blundell with his usual sagacity had suggested that it might be done, but Simpson pronounced it unjustifiable in 1860. Modern improvements have enabled us to advise such operations. Abscess of ovaries, salpingitis, and other points were discussed and the president remarked that most of the pioneer work had been done by Continental obstetricians and surgeons, the British generally following rather than leading. The provincial surgeons have kept rather ahead of the London schools and Mr. Spanton thought the time had now arrived when the scientific teaching of gynecology so long well carried out in the provinces should be adopted in a whole-hearted way in the metropolitan hospital schools. He hoped the time would come when more liberal ideas would prevail and the proper place of extramural practice and teaching be recognized by examining boards.

A memorial to the late Dr. Schorstein of the London Hospital is being raised in connection with the Medical School. It is proposed to found a lectureship in advanced clinical medicine, not as a part of the ordinary curriculum,

but rather on the lines of the endowed lectureship at the Royal Colleges, three or four lectures by a physician to be elected on each occasion by the governing body, due notice being given to afford time for the lecturers to prepare a discourse worthy of the subject and of the late Dr. Schorstein. At present the governing body is the College Board, representing two interests, the hospital managers and the staff. A more suitable body for selecting the lecturer might well be chosen.

Mr. Henry Morris, P.R.C.S., presided at the annual meeting of the Middlesex Hospital yesterday. The report of the Clinical and Bacteriological Laboratories testified to the excellence of the work carried on in them and indicated that the facilities afforded by the clinical investigation department were greatly appreciated by practitioners. The financial statement was satisfactory as hospital reports go. There was a slight increase in the patients admitted to the cancer wards during the year. The report was adopted and after the formal business a testimonial to one of the hospital nurses was presented. It appeared that Nurse Cross was in Jamaica when the earthquake took place and assisted Dr. Arthur J. Evans on board the *Port Kingston* for nearly forty hours consecutively in rendering surgical aid to over 200 injured persons. Her conduct had been brought before the Board and the framed testimonial was presented setting forth that "her fortitude and noble devotion signally redound to the honor of the nursing profession and of British womanhood."

At the annual meeting of the Royal National Orthopedic Hospital on Wednesday it was stated that the amalgamation scheme was working well and that when the new building is erected it will be the most complete hospital of the kind in the world. It is hoped that the foundation stone will be laid within a few months. In the meantime three vacant wards at Charing Cross Hospital have been rented and some property adjoining the old hospital purchased to utilize during the rebuilding.

At the meeting of the Cancer Hospital held Wednesday it was reported that a deputation of the staff attended the Congress at Heidelberg and visited many institutions in Germany, Denmark, and the Netherlands to study the methods of treatment. There had been a considerable increase in the research and pathological department during the year. In the report of the Medical Committee special attention was drawn to an instruction issued to patients advising early recourse to medical advice, as cancer often begins as a small, painless lump.

The meeting of King's College Hospital was also held yesterday, the Hon. W. F. D. Smith in the chair. The ordinary expenditure for the year had been £22,315, an increase of £827 over the preceding year. This was due, according to the report, to the reassessment of the premises at a considerably higher figure which had increased the amount of rates and taxes by £216, and to exceptional allowances on retirement. The ordinary income was £16,081, as against £16,200 in 1905. There had been a further decrease of work in the out-patient department, the change in the neighborhood accounting for this—a result, I may add, which is by no means to be regretted.

Cerebrospinal fever still seems spreading. Three or four cases have been received in London hospitals. Compulsory notification has been adopted in most places where it appears. The Scotch and Irish cases continue to increase.

OUR BERLIN LETTER.

(From Our Special Correspondent.)

TRYPANOSOMIASIS—INJURIES THROUGH ELECTRICITY—INFANT FEEDING—THE PROFESSION IN GERMANY.

BERLIN, February 17, 1907.

On February 14 an event of more than usual interest occurred in the history of the Berlin Medical Society. Every seat in the large auditorium of the Society was occupied and the audience listened with the greatest attention to a discourse by Paul Ehrlich of Frankfurt in which he described his experimental studies on sleeping sickness. The speaker took the occasion to dwell especially on the method of experimental therapy, which he so warmly advocates. In all diseases it should be the object to seek to discover remedial agents which shall be directly hostile to the causative agent and combine with it. Such substances are called bacteriotropic or etiotropic by Ehrlich. If they are also taken up by the tissues of the body they may be termed organotropic. After it had been discovered that the manifestations of trypanosomiasis in animals were very similar to those in man, hundreds of remedies were tested and two particularly potent bacteriotropic substances were discovered. One of these is a dye called trypan red. For most of the experiments the trypanosomes used were those causing the South American *mal de caderas*. The strain under observation killed mice in four to five days, but if trypan red was injected into the animals the day after the inoculation they remained healthy. If, however, a few of the organisms escaped the action of the drug, a fatal termination ensued in the course of a few weeks. There were some strains of trypanosomes that were not affected by the trypan red but which were found by Laveran to be susceptible to a combination of trypan red with arsenic. Malachite green and brilliant green, two aniline colors, were found also to possess toxic properties for the trypanosome, but owing to their irritating nature these agents were not available for practical use. Apparently the simpler the chemical composition of a dye stuff, the less irritating was it likely to be. The speaker had found that the experiment mice exhibited considerable variations in their powers of resistance to the parasites; each mouse, so to speak, had its own titer of susceptibility. The biology of the trypanosomes has so far not received much attention from the therapeutic standpoint. By giving fuchsin to mice Ehrlich found that the immunity produced became of shorter and shorter duration, showing that the parasites became habituated to the poison. In this manner it was found possible to produce a strain which was resistant to fuchsin, and also strains that were refractory to trypan red and trypan blue. The tediousness of these experiments was evident from the fact that some of the strains were already in their one hundred and eightieth transfer. The variations in the therapeutic results obtained by observers in different countries could be explained on the ground that the various types of the parasite encountered might be more or less resistant. It was therefore necessary for laboratory workers to determine the powers of resistance of their cultures and in cases in which the arsenic treatment was found inadequate to combine it with the administration of trypan red. As it was found that trypan blue was just as effective as trypan red, search was made for the active component present in each and it was discovered in a sulphur radical common to both.

Another address by a stranger was that delivered by Jellineck of Vienna before the Society of Internal Medicine on the pathology, prophylaxis, and treatment of accidents by electricity. He first called attention to the fact that unipolar contact was sufficient to close an electrical circuit owing to the constant presence of electric currents in the ground. In dealing with atmospheric shocks, true and false lightning strokes were to be distinguished. The effect of the lightning discharge was the result of a combination of the actual electric current itself and of the destructive action on the surrounding objects struck. It might also be conveyed to a distance through such agencies as telephone or telegraph circuits. The electric discharge began to be dangerous even at a tension below 100 volts and the continuous current was more hazardous than the alternating current, because the first was drawn directly from the power house without the intermediation of a transformer. Individual differences in resistance might also play a part in different persons, and the resistance also varied in different parts of the body. The character of the flooring was of importance, a stone paved floor offering the greatest resistance. An interesting case was one that occurred in Vienna in which a young girl was killed through catching hold of an incandescent light while in the bath tub. In this instance through leakage in the wiring the circuit was closed through the body of the girl, the bath tub, and the floor. The experimental observation that anesthetized animals were aroused by a certain current but that the same current sufficed to kill animals in the waking condition held good for human beings also. Sleeping persons undergoing powerful electric shocks were simply aroused, but waking individuals were killed. The speaker had seen seventy-five cases of lightning stroke and one hundred and fifty-seven accidents from the electric current, and he related several interesting case histories. Lumbar puncture has been found useful in dealing with severe cases of electrical injury.

A dissertation of practical importance that was also interesting on account of the side light thrown on social conditions in Berlin was presented by Neumann before the Berlin Medical Society on January 30. His subject was the natural feeding of infants in medical practice. He admitted that many healthy children did well on artificial feeding but that in dealing with prematurely born or weakly infants breast feeding was necessary in order to avoid intestinal disturbances. If rachitis existed in the family, only through breast feeding was it possible to prevent the lesions caused by this disease. Children born in the second six months of the calendar year ran the greater risk of becoming rachitic. In Berlin in the year 1900 only 30 per cent. of nursing mothers were found in families that occupied homes consisting of more than four rooms, but it was determined that from 70 to 80 per cent. of the mothers were physically able to nurse their children. Artificial feeding was resorted to chiefly because the mothers

did not realize the dangers of it, and therefore the medical profession should make greater efforts to disseminate knowledge on this subject. The greatest danger, both in artificial and natural feeding, lay in overfeeding, and in some cases the common practice of feeding by the clock was too schematic.

Statistics of interest in regard to the medical profession in Germany have been collected by Dr. Prinzing. The total number of physicians is now 30,931. The absolute number has become larger, but on account of the great growth in population the relative proportion has diminished, so that apparently the increase in the number of physicians observed during the last twenty years has been checked. In Prussia and some other German states, three to seven physicians are found for each 10,000 inhabitants, but in the large cities, there are seven to twenty. In 1901 there were 2,786 physicians in Berlin and in 1906 there were 3,196, but the relative number has remained about the same, that is, 12.1 per 10,000 inhabitants. The number of specialists has increased greatly and now from a third to one-half of all the physicians in Berlin, Munich, Dresden, and Frankfurt are specialists. Among the specialties gynecology is the most followed, except in Berlin, where genitourinary specialists take the lead. Even the smaller towns are filled with specialists and it seems advisable to warn young physicians against attempting to devote themselves to a single subject.

OUR VIENNA LETTER.

(From Our Special Correspondent.)

A NEW TREATMENT OF DEFORMITIES OF THE LOWER EXTREMITIES—OBSERVATIONS ON PERLSUCHT—TEMPERATURE DETERMINATIONS BY MEANS OF THE URINE—ECHINOCOCCUS OF THE LUNG—FOREIGN BODY IN THE ESOPHAGUS.

VIENNA, February 15, 1907.

A NEW and very ingenious method for the treatment of flat foot, club foot, knock knees, and bow legs was recently described by Semeleder before the Medical Association. He presented a number of patients who exhibited the astonishingly good results to be obtained by this method. The speaker pointed out that the customary procedures were painful and time-consuming and that the results obtained were no better than those promptly secured by the painless use of his appliance. The apparatus was not visible while in use, since it was contained in a shoe that did not differ in appearance from an ordinary one. Semeleder had the following to say in regard to the way in which he came to devise his appliance: The well-known fact that continuous standing and walking tended to aggravate a condition of flat foot, whereas the opposite of flat foot, the club foot, was increased in the same way, led the speaker to consider whether the pressure which ordinarily had a deleterious action might not be transformed in its effect so that in flat foot it might tend toward the production of club foot, and vice versa. If the process of correction were arrested at the right moment, that is, when the opposite deformity had been half produced, a normal foot might be secured from either one. After experiments had been carried on for years a simple appliance had been devised by means of which simple walking was made more effective than the most careful massage. The function of the shoe was to perform auto-massage through the alteration in the direction of action of the pressure while walking. The most valuable feature of this massage was that it was self-regulating, since it was controlled by the patient's weight, the weight of his step, and the amount he walked. Under all these conditions the correcting forces always corresponded exactly to the demand, since no force was brought into action except the pressure of the step, the direction of which force had simply been properly altered.

Observations on *Perlsucht* have been continued by J. Bartel in Prof. Weichselbaum's laboratory. If *Perlsucht* bacilli are injected into rabbits and the animals are killed and portions of their organs inoculated into other rabbits, these animals die of tuberculosis and their organs are found full of tubercles. The same thing occurs if the bits of tissue are preserved for some time in blood serum. On the other hand, if the material to be inoculated is kept for some time in the incubator before the inoculation is done no tuberculosis appears in the experiment animals. Rabbits that had been intraperitoneally inoculated with *Perlsucht* bacilli died some time later of generalized tuberculosis, and advanced tuberculous changes were found in their internal organs. Rabbits, however, that had been treated for several months previously with attenuated tubercle bacilli did not become tuberculous on inoculation in the same way. The experiments showed that not every infection with tubercle bacilli is necessarily followed by tuberculosis, because the body may have previously acquired a general or local immunity through the entry into the body of attenuated tubercle bacilli.

In order to determine bodily temperature Englander takes the temperature of the urine while being voided. To do this he has the patient urinate into a funnel made of strong filter paper and having its point cut off. The thermometer is placed in this funnel and is kept in position by cutting a suitable supporting slip from the paper. The advantage of the method lies in its simplicity, as the determination may be made in a few seconds and accurate results are obtained both at room temperature and at very low temperatures. Owing to the short time necessary for the determination and the poor conducting power of the paper funnel, the urine undergoes only a practically imperceptible cooling. Comparisons of results obtained by this method with those gained by the ordinary procedures showed that there was perfect correspondence between the urine temperature and the rectal temperature, whereas the axillary temperature was sometimes as much as one degree lower. Determinations of the urine temperature demonstrated the daily physiological fluctuations in temperature, that is, a rise toward the afternoon followed by a fall lasting until the morning hours, as well as the elevation of temperature produced by muscular work. The method is especially suitable in dealing with patients who are up and about and for scientific purposes.

A case of primary echinococcus of the lung has been cured by Herczel by resorting to pneumonotomy. The patient was a boy of nine years who fifteen months previously had had pneumonia and three months later had suffered from pleurisy. A quarter of a year after this, severe attacks of coughing ensued accompanied by profuse expectoration without tubercle bacilli and moderate elevations of temperature. An exploratory puncture gave a negative result, though it was followed by fever and night sweats. It was then noticed that the left side of the child's thorax was larger than the right and dullness was discovered below the angle of the left scapula. It was supposed that the case was one of encapsulated empyema and the Roentgen ray revealed a sharply circumscribed shadow. It was decided to operate and portions of the seventh and eighth ribs 9 cm. in length were resected. Clear fluid was obtained from the lung on puncture and it was evident that an echinococcus cyst was present. The cyst was incised and its wall was found adherent to the parietal pleura. By careful manipulation the production of pneumonthorax was avoided and on further investigation it was found that the mother-cyst communicated with a bronchus. The large cavity was packed with gauze and the skin flap sutured in position. Seven days later severe urticaria appeared which persisted for three weeks in spite of all treatment. At the end of the seventh week only a small sinus remained which closed completely a month later. A recent radiograph showed normal conditions.

Much interest has been aroused by an operation performed in Prof. Chiari's clinic. A man of thirty-eight years applied for treatment, saying that about a month before he had swallowed his artificial teeth while asleep. At first he had suffered from severe dyspnea, but this soon subsided again. At present he was able to take only fluid food, but he had no actual pain. On examination an obstruction was found in the esophagus and radiographs made in Prof. von Eiselsberg's clinic showed a shadow resembling the false teeth at the level of the first dorsal vertebra. The attempt was then made to extract the foreign body without opening the esophagus and by ingenious manipulations with various tubes the operators succeeded in withdrawing the plate without using undue force. This was all the more remarkable as the plate was one of five teeth and measured 4.5 cm. by 2.5 cm. At present the patient is perfectly well.

OUR LETTER FROM THE PHILIPPINES.

(From Our Special Correspondent.)

DECLINE IN THE NUMBER OF LEPERS—CARE OF LEPERS IN THE PHILIPPINES—ANGOSA, OR RHINOPHARYNGITIS MUTILANS—COLD WEATHER IN THE PHILIPPINES—MEDICAL INSPECTION OF THE PUBLIC SCHOOLS—RESIGNATION OF DR. DE MEY.

MANILA, P. I., February 1, 1907.

AN analysis of the tables prepared by the Bureau of Health of the number of lepers in the Philippines, shows that there has been a steady decline in the number of lepers reported. For the year ended August 31, 1904, there were 3,623; for the year ended August 31, 1905, there were 3,580; for the year ended August 31, 1906, there were 3,404; for the quarter ended September 30, 1906, there were 3,473, and for the quarter ended December 31, 1906, there were 3,225. The decline has been most noticeable during the last six

months of 1900. It is believed that the reduction in the actual number is really greater than the figures show, because the sanitary organization in the Philippines is undergoing constant improvement, so that many cases that would have escaped attention entirely a few years ago, now find their way into the official records. From a casual examination of the figures it is, of course, impossible to say whether the reduction is due to the improved sanitary methods now being gradually and steadily extended by the American Government, or whether it is due to some cause not yet well understood. On account of the reduction having been so marked during the last six months of 1906, it would appear that the decrease can at least be attributed in part to the many centers of infection which were obliterated during that period. It will be remembered that effective segregation and isolation of lepers in the Philippines did not begin until May, 1906, and it is only from that date on, that the beginning of the solution of this problem can be counted.

For the past several hundred years, the care of those who were unfortunate enough to contract leprosy, has received considerable attention in the Philippines, but a careful review of the history shows that it was more or less of a charitable nature, and not carried out in such a way that the final disappearance of the disease could be hoped for. It was the practice to admit to leper hospitals those lepers who were unable to earn a living, or who had no one to provide for them. This left many lepers at large who managed to make a living by begging or by the charity of kindly disposed individuals. Thus, the few hundred lepers who were actually confined to an institution had very little effect upon reducing the number of infected foci upon the outside. The real solution of the problem must, therefore, date from the time of the American occupation, and more especially from the time the Civil Government set aside an island for this purpose and began the construction of suitable buildings and quarters for their isolation.

The first person in the Philippine Islands definitely known to have been afflicted with gangosa, or rhinopharyngitis mutilans, which is the name suggested for the disease by the Navy medical officers, died at the St. Paul's Hospital, this city, last week. Cases may have occurred in the past, but they have escaped recognition, and extensive inquiry among Filipino and Spanish physicians who have been in the islands for many years, tends to show that while cases of a disease with similar symptoms have been observed, yet, they were generally regarded as leprosy, and no distinct separation was ever made.

In the description given by Surgeon J. F. Leys, United States Navy, which appeared in the annual report of the Surgeon General of the Navy for 1905, it is stated that gangosa is an infectious, painful, repulsive, and disfiguring disease, the cause of which is not known, and which prevails extensively in the Island of Guam. The nose and upper part of the face are destroyed by slow ulceration, while the tongue is never affected. Cases have been observed in persons from three to eighty years of age. The disease sometimes lasts from several months to a number of years, and even during this period, in its active stage, there is no reduction in the flesh or strength. The mortality of the disease is low. The disease is not very amenable to treatment, although antiseptic methods appear to retard the extension of the ulceration. It is estimated that there are about 200 persons on the Island of Guam who are afflicted with gangosa.

The Philippines, during the month of January, have enjoyed an unusual amount of cool weather. The Weather Bureau has reported that this has been the coldest January since 1857. In the mountains of Benguet, near the Benguet Sanitarium, and the place where the summer capital of the Government is located, the Weather Bureau reported that the thermometer actually registered 28° F., and ice to the thickness of one-quarter of an inch formed in exposed places.

A few weeks ago the systematic medical inspection of the public schools of Manila was commenced. It is yet too early to state what the result of this inspection will be, but from the preliminary reports received, it appears that much the same conditions exist among the Filipino school children as are found among American school children in the larger cities of the United States.

Dr. C. F. de Mey, who has been the chief of the Culion Leper Colony Division of the Bureau of Health for the past few years, and who was in direct charge of the construction of the colony, has resigned his position and will soon proceed to France, where he expects to practice his profession.

An Edict Against Corsets.—The Bulgarian Minister of Public Instruction has prohibited the wearing of corsets by the pupils in the girls' schools of the principality. The penalty is expulsion from school.

Progress of Medical Science.

New York Medical Journal, March 9, 1907.

Clinical Observation on the Use of Cotarnine Phthalate.—The use of this remedy as a uterine hemostatic is highly commended by C. A. von Ramdohr. Cotarnine is a derivative of narcotine from opium. The new salt is a yellowish crystalline powder freely soluble in water. It may be given in coated tablets in doses of three-quarters of a grain, from 3 to 9 tablets being the daily limit. It acts on the vasomotor uterine nerves. So far no toxic effects have followed the maximum dosage above indicated. It is not indicated in cases calling for hurried uterine contraction. The author has found it superior to ergot and cotton-wood. Brief histories of its results in six cases are given.

A Case of Cancer Treated by Trypsin.—W. J. Morton reports the case of a woman of forty-five years with a lump in the breast, *x*-ray treatment, radioactive water, and fluorescin reduced it one-third in size, and still later to a mass the size of the end of the thumb. This was removed under cocaine and proved to be a highly fibrous scirrhus carcinoma. Later two new nodules appeared, one below the clavicle, near the shoulder tip, and one under the chin. Trypsin and amylopsin injections were used with success, and some twenty months later the patient was reported as doing well.

Indigestion; Its Significance and Diagnosis.—H. F. Stolt refers to the various causes which may produce gastric symptoms, although the stomach is not the organ primarily at fault. Our errors in diagnosis may be due to (1) incomplete history of the case; (2) failure to make a complete examination; (3) stopping our search for the cancer with the discovery of the first lesion, and (4) the omission of special tests. The author calls attention to the necessity of method, system, and completeness in our search for the cause, and then takes up the diagnosis of some of the more common gastric maladies, as, ectasy ulcer, cancer, gastric hyperesthesia, and nervous dyspepsia. He notes that there is probably no class of patients in whom less attempt is made at an accurate diagnosis than in the dyspeptics. They enter the office with a tale of woe concerning their indigestion and they are given a prescription for some much advertised preparation which "cures all kinds of indigestion," when an inspection of the mouth might have revealed a few scattered teeth, or the passage of the stomach tube have demonstrated the food of former days. Rational therapeutics can only follow careful diagnosis.

Value of Differential Leucocyte Counts in Medicine.—J. S. Wile summarizes the definite knowledge at our command as to the value of the leucocyte count in disease. Nothing new is brought forward. He believes that it affords more suggestive information than any other procedure in blood analysis. He also discusses the prognostic value of eosinophiles, noting that in most infectious diseases accompanied by neutrophilic leucocytosis there is a diminution of eosinophiles. The return of eosinophiles to the circulation after a primary decrease or absence is of good prognosis. The reappearance of the eosinophiles foretells approaching convalescence. On the other hand, a sudden fall of the eosinophiles during the course of an infectious disease where they were previously present suggests some complication which is interrupting convalescence. This prognostic value of the eosinophiles holds true in pneumonia, typhoid fever, appendicitis, and septic processes. Generally speaking, when mentioning leucocytosis we refer to the condition of the blood where there is a relative or absolute increase of the neutrophilic leucocytes. The author calls attention also to the necessity of taking the age of the patient into account in interpreting our differential findings. The percentages of the various types of leucocytes do not approximate the percentages normal in adults before the ninth year. At one year the lymphocytes average about 54 per cent., the neutrophiles only 35 per cent. In adult life the neutrophiles form 60 per cent., and the lymphocytes 35 per cent. of the total leucocytes. Hence, 65 per cent. neutrophiles in a child, six months old, may represent a pronounced leucocytosis, whereas it would be perfectly normal in an adult.

Journal of the American Medical Association, March 16, 1907.

Quinine Injections and Tetanus.—Having had his attention called recently to a severe case of tetanus following an injection of quinine hydrochlorate, E. F.

McCampbell reundertook a series of experiments previously performed by him to test the conclusions of Vincent that the injection of quinine had a favoring action on the development of tetanus. His earlier results were entirely negative and he therefore carefully followed up Vincent's claim and here reports the results of two carefully conducted series of experiments. He finds that the salts of quinine have a feebly antiseptic action on the spores of tetanus, that of the hydrochlorate being the greatest. The lethal dose of neutral hydrochlorate of quinine is from 1/3500 to 1/4000 of the weight of the guinea pig and from 1/4000 to 1/5000 of the weight of the rabbit. The dose varies with the age, young animals being most susceptible. Hydrochlorate of quinine has a paralyzing effect, varying in different animals, which McCampbell attributes to the coagulating action on the protoplasm of the peripheral nerves. Atrophy of the extremities results after long doses. In cases of tetanus in experimental animals which had been injected with hydrochlorate of quinine the disease resulted only in those cases in which there was a mixed infection. The quinine may have aided by its corrosive action in favoring this secondary infection, and it is possible that it may have acted as an additional irritant to the nervous system, rendering it less resistant, but any other mild corrosive substance could act the same way. In cases in which tetanus did not result after injections and there was no secondary infection, the spores had evidently undergone phagocytosis by the leucocytes or tissues, as none of them were ever found. Hydrochlorate of quinine is unable to favor a tetanus infection other than in the above indirect way. It has not the power to awaken an infection when injected at the same time with the tetanus spores or at other times. It causes a slight leucocytosis and has a slight paralyzing effect on the leucocytes. If this were so extensive as to involve the majority of the leucocytes of the body, it is possible that the spores of tetanus might develop unhindered, as is the case when lactic acid is injected; but in that case the toxic effects of the quinine itself would be manifested and would probably cause the death of the animal. McCampbell believes that in most of the cases in which tetanus has followed quinine injections it can be traced to some fault of surgical technique or to some contamination of the quinine solution. The tissue necrosis from the quinine injection would favor infection by tetanus germs as well as by other bacteria. He does not think that there is sufficient proof that the tetanus spores can be transported from point to point according as the quinine is injected, nor that it is possible for the healthy living spores of tetanus to be present in the body and to develop a severe and fatal infection on the advent of an injection of hydrochlorate of quinine.

Malaria.—W. Krauss says that no region should be uninhabitable on account of malaria and that much of the so-called malaria is something else. He asserts that he has seen tuberculosis, sepsis, gall-bladder disease, liver abscess, dysentery, uncinariasis, chronic nephritis, and visceral malignant disease, in persons who come to him, all with the same story of "malaria in the system." Nothing is more amenable to proper treatment than malarial fever, he says, and a recent infection is almost never anything but a fever. Malaria in the beginning is an infection by one or more groups of one or more varieties of blood parasites whose life function in the body is the destruction of hemoglobin. The segmentation of these parasites starts the well-known symptoms. A resistance is developed and the so-called chronic malaria is, as Krauss believes, a state of relative immunity in which repeated infections produce comparatively slight reactions, a state of symbiosis in which the immunizing contest between the parasite and the blood-making organs is in a state of equilibrium. So long as the patient remains in a malarial climate the condition may become acute through reinfection, especially when assisted by outside influences. The merozoites resulting from segmentation, according to this theory, do not invade new cells, but hibernate somewhere in the organism and become active when reinforced by a new infection, or die when the patient removes to a non-malarial climate, but they do not, *per se*, he declares, produce any paroxysms. Krauss holds that in these cases of chronic malaria without paroxysms or marked cachexia, quinine, as well as other factors disturbing the symbiosis, may produce symptoms of intoxication, including hemoglobinuria. The only time to give quinine is when developing parasites are found in the peripheral blood, provided also that the infection is fresh, as shown by a characteristic fever curve. It is his practice in the autumn to give two or three 10 or 15 grain doses of sodium thiosulphate at desirable intervals until the bowels are freely emptied. Pernicious cases must of course be treated more expeditiously. He advocates especially frequent blood examinations of persons living in malarial districts, even if well. His conclusions are given as follows: "1. There is not the shadow of an excuse for failure to make an exact diagnosis in all fever cases. 2. The blood of residents of malarial localities should be examined at frequent intervals. This does not constitute an encroachment on personal liberty that can weigh a feather's weight as compared with vaccination. 3. Fever cases should be treated in accordance with the findings of a thorough blood examination, with special reference to time of dosage and to the complete immunization of the individual for the sake of his neighbors. 4. Quinine judiciously used in accordance with findings of a blood examination very rarely does harm; its prohibition on the ground of possibly producing a hemoglobinuria is unpardonable; its administration during hemoglobinuria is very dangerous and usually unnecessary; a blood examination will save such patients from almost certain death. 5. The screening of houses and the destruction of breeding places of anopheles should be encouraged so far as possible, but the prophylaxis of malaria and its definite local eradication depends on the destruction of the parasite within its alternative host, man."

The Pretuberculous Stage of Consumption.—C. F. Beeson calls attention to the earliest symptoms of pulmonary tuberculosis before the physical and rational symptoms have become fully manifest. After noticing the usually recognized characteristics of the phthisical predisposition, he mentions as the signs of incipient consumption an over brightness of the eyes, with possibly slight inequality of the pupils due to reflex of the ciliary nerve from apical irritation, brittleness of the hair, variable and uncertain appetite, fluctuations in body weight, quick fatigue, subnormal morning temperatures slowly reached by the thermometer, chest pains, frequent clearing of the throat, and husky expiratory cough; there may be a bluish tinge to the lips or an unusual redness of the gum margins. Careful inspection may reveal deficient expansion of one or the other apex, or the Litten shadow may not fall as it should. A prolonged expiratory sound may be heard at or near an apex, and there is sometimes also a fine laryngeal crepitus to be heard by placing the ear near the open mouth of the patient. Sooner or later a slight hemorrhage or a prolonged "cold" will startle the patient and be what he, and too often his physician, considers the starting point of pulmonary tuberculosis.

Passage of Methylene Blue from the Mother to the Fetus.—S. H. Corrigan reports the observation of a healthy new-born infant whose urine for the first eighty hours after birth left a blue stain on the diapers, the color gradually disappearing. The mother had been taking methylene blue during a large part of her pregnancy for chronic cystitis. There was no evidence of the drug in the liquor amnii nor any trace of it on the sheets or pads used during labor. From these facts he assumes that methylene blue passes from the maternal to the fetal circulation, and, there being no evidence of it in the liquor amnii, the fetus does not evacuate the bladder before birth, and its kidneys do not excrete it beyond the amount contained in the bladder at the time of birth.

The Lancet, March 2, 1907.

Streptococcus Wound of the Finger.—W. P. Cowes reports the case of a man of forty-four years who, while sparring with a fellow workman, struck the back of the right index finger against his opponent's tooth, making an incised wound. He was seen four hours later. Examination showed a wound on the index finger just posterior to the first knuckle; this was seared over. There was no other wound found nor were there evidences of any septic places around the hand. On opening the wound pus was seen. A cover-glass preparation was made and a culture was taken. The wound was douched, very slightly enlarged, touched with carbolic acid and alcohol, and drained. The finger did well and the man was soon discharged. The cover glass showed numbers of streptococcus and the culture was a pure one of that germ. The interest in the case lies in the unusually short period of incubation—namely, four hours.

Rupture of the Aorta and Rupture of the Left Ventricle.—R. A. Forster's first patient was a woman of seventy-nine years, slightly demented and confined to bed three weeks with bronchitis. Death came on suddenly without apparent cause. Autopsy showed pul-

monary emphysema, pericardial sac full of serum and clot, and a large rent in the lower and posterior walls of the aortic arch, measuring three inches in length and extending round three-quarters of the circumference of the vessel. The blood had evidently broken through the inner and middle coats of the aorta, dissected its way down into the tissues between the aorta and pulmonary artery, and finally at the origin of the latter vessel from the heart had burst into the pericardial sac. The walls of the aorta were thinned and showed some small atheromatous patches, though there were no marked signs of degenerative changes. The valves of the heart were healthy and competent. His second patient was a man of fifty-nine, also demented, with atheromatous vessels, dying suddenly. Autopsy showed left lung collapsed, and clot and serum on the pericardium. A rupture, measuring half an inch in length, was present in the anterior wall of the left ventricle, close to the intraventricular septum and midway between the apex and base of the ventricle. The edges of the rupture were ragged and the hole through the ventricular wall was cone-shaped, the base of the cone being the external opening. The heart muscle was flabby, but there was no naked-eye appearance of fatty degeneration. The aorta was atheromatous and numerous calcified plates were seen in its walls. The descending branch of the left coronary artery was almost completely occluded at its origin by atheromatous degeneration of its walls, and at this point the vessel was of a stone-like hardness. This branch was traced down to the site of rupture and evidently the myocardium, deprived of its blood supply by the atheromatous obstruction, had undergone the necrosis spoken of by Ziegler as myomalacia cordis. The wall of the ventricle thus weakened by the necrosis had given way.

Intestinal Obstruction in Children.—Two cases are reported by E. P. Bauman. Case 1 was one of acute intussusception, reduced by manipulation, and Case 2 one of subacute intussusception simulating dysentery. The first case completely recovered, while the second called for surgical intervention, and abdominal incision was made. The patient had gone into collapse at the time and died in two hours. The features of the second case, which, in the author's view, are noteworthy, were, first, the comparative rarity of these cases of incomplete intussusception in which the occlusion of the bowel is incomplete and the passage of feces continues unimpeded, while there is little or no vomiting. These cases may last for weeks or become chronic and exist for months or years, death in most instances being due to exhaustion. Secondly, there was a considerable amount of hemorrhage from the bowel. Usually, in subacute or chronic intussusception, the catarrhal changes at the neck of the involution are comparatively slight and the stools are characterized only by small hemorrhages. Thirdly, there was the similarity to a case of dysentery—superficial, it is true, yet sufficiently exact to obscure the diagnosis. Fourthly, there were the disappearance and reappearance at intervals of the abdominal tumor. According to Treves a tumor is felt on abdominal examination in only fifty per cent. and rectally in only thirty-two per cent. of these cases, and in the paper already quoted the author calls attention to the recognized fact that the tumor, once it has been felt, may disappear from time to time. For this reason it is essential that the examination of the abdomen should be undertaken both thoroughly and repeatedly. Fifthly, the fact that another child of the same family should also, and at about the same time, have passed blood-stained motions was perhaps the most perplexing factor of this difficult case.

British Medical Journal, March 2, 1907

Two Cases of Cystin Calculi.—F. A. Southam presents histories of two cases of this rare occurrence. In the first patient, a man of thirty-two years, the stone which gave the usual symptoms and was easily detected by sounding the bladder was removed by suprapubic lithotomy and the patient made a good recovery. The stone had the shape of a mushroom, one and three-quarters inches by one and a quarter in measurement, and was of a pale color, with an irregular crystalline surface. Cystin crystals had intermittently appeared with urine. In the second patient, a girl of twenty-two years, the stone had been passed per urethra. It was of a pear-shape, one-third of an inch in length.

Influenza Commencing with Sudden Unconsciousness and Excessive Dyspnea.—The patient of W. Harris was a man of thirty-eight years, plasterer, admitted to hospital, who had fallen unconscious while at his work and had slight convulsions. He recovered in about twenty minutes, so as to speak, and came to the hospital in a cab. He presented a moderate fever, slow pulse, legs were somewhat stiff, while respirations were very frequent—about sixty per minute. He also complained of severe frontal headache and of pain in his back in the lumbar region, and he was able to tell us that he had had two similar attacks, one four years and the other fifteen years previously. Examination of the chest showed him to be perspiring freely; both sides of the chest moved well, but on percussion the note over the whole of the right front was distinctly high-pitched, and there were numerous sticky râles to be heard over the right upper lobe. The arteries were somewhat thick-walled and hard, but the urine was of good specific gravity, and contained no albumin. The optic discs and retinæ were normal, and examination of the nervous system showed no abnormal physical signs. Tentative diagnosis were epilepsy, cerebral tumor, hemorrhage, or thrombosis, uremia, and pneumonia. The author details the reasons which led him to reject all these and come to the conclusion that the man had influenza, attaching great value to the slow pulse (56) with a temperature of 99.6°. Looking at the case from this point of view, the other symptoms—the frontal headache and lumbar pain, pyrexia, sticky râles, and cough—all clearly pointed to this disease. Only the curious mode of onset with sudden unconsciousness remained to be explained, but, being familiar with the literature of the disease, particularly of the epidemic of the early nineties, the author was aware of several cases having been recorded which started suddenly in this way. The after-course of his case proved this diagnosis to be correct.

Idiopathic Dilatation of the Colon.—H. F. Hawkins makes a study of a series of cases collected mainly from the records of St. Thomas' Hospital. The main features of the cases have grouped themselves as follows: (1) A history of constipation from birth or from the earliest recollection, which is compatible, however, with fairly good health, until the final stage is at hand, the first sign of failure being often a loss of weight. (2) A constipation which often alternates with diarrhœa, and which at its worst is unlike that of obstruction, inasmuch as flatus is often passed and fecal matter may be drained away through a rigid rectal tube. (3) Abdominal enlargement, variable or constant, often asymmetrical, with prominence in the left iliac region, the abdomen, though distended, being seldom tense and often surprisingly flaccid, and rarely presenting any impairment of resonance. (4) Slow alterations in shape, especially in the left iliac region, observable only with patience, quite unlike the tense peristalsis seen in real obstruction. (5) The absence or rarity of pain and vomiting. Neither with real intestinal obstruction nor with simple nondilating constipation should there be any confusion when this condition is far advanced. The difficulty lies in distinguishing its early stage from a simple constipation, and in recognizing the point at which the case must pass from physician to surgeon. The author then goes on to consider the origin of the condition, finding both an anatomical and a nervous factor in its production, and studies the anatomical morbid conditions found in the various portions of the gastroenteric tract. He closes with summarized accounts of the various cases on record.

Berliner klinische Wochenschrift, February 18, 1907.

The Treatment of Subcutaneous Injuries of the Pancreas.—Karewski says that severe, isolated, subcutaneous injuries of the pancreas are among the rarest of abdominal lesions. Garré in 1905 was able to collect records of about thirty subcutaneous tears of the gland, of which only three were uncomplicated. To these, three others may be added which have been reported since that time, and out of this total of eleven only three patients were saved, in each case through prompt laparotomy. The author describes a case of his own which also terminated in recovery. The patient was a boy of fifteen years who received a blow in the abdomen from a wagon pole while riding a bicycle. He was able to walk home, but soon after went into collapse. At the operation the head of the pancreas was found in a crushed condition, and there was a moderate subperitoneal hemorrhage. The pancreatic injury was packed and the incision partly sutured. The boy made a good recovery except for the persistence of a sinus, which discharged pure pancreatic juice, and did not close for nearly three months. In the after treatment careful observations were made on the influence of diet on the character of the discharge from the sinus, and it was found that, by resorting to a diet rich in meat and fat but poor in carbohydrates, the juice became concentrated and very scanty. By continuing what was practically a strict diabetic diet

the closure of the sinus was finally secured, and the author recommends this plan as an important feature in the management of such cases.

Munchener medizinische Wochenschrift, February 19, 1907.

The Operative Treatment of Laryngeal Stenosis.—Wendel says that fractures of the larynx, while comparatively rare, are serious injuries which tax the ability of the surgeon, partly on account of their immediate dangers, and partly on account of the risk of permanent impairment of the functions of the larynx. Of seventy-five cases reported by Fischer, the mortality was 70 per cent. Durham found a mortality of 77 per cent. in sixty-nine cases, but the more recent figures of Hopmann show a mortality of 37 per cent. out of seventy cases. The author describes a case of his own in which a young man fell against the edge of a box and sustained a fracture of the thyroid cartilage. The immediate consequences were severe, but were successfully combated by a tracheotomy, but in the process of repair a serious degree of stenosis of the larynx resulted. This was partly due to adhesions between the posterior halves of the two vocal cords, but on incising these it was discovered that a dense cicatricial band just below was the chief factor in the constriction. A laryngotomy was accordingly done, and it was seen that there had been some displacement of the fragments, so that in the course of their union an oblique distortion of the larynx was produced. The author describes the rather complicated method in which the defect caused by the excision of the cicatricial tissue was covered in with mucous membrane, and states that the patient recovered completely with a well-functionating larynx, though slight hoarseness persisted.

Specific Solubility and Its Applicability in Forensic Blood Tests.—Dehne points out the possibility of practically making use of a property of homologous blood sera in connection with antisera. This phenomenon, which was first noted by Michaelis, consists in the fact that specific precipitins formed as the result of the union of antiserum and antigen are soluble in an excess of the latter. Dehne describes observations made in order to test the validity of the principle laid down by Michaelis, and arrives at the conclusion that the solubility of the precipitin in the antigen is a specific phenomenon, for which he suggests the term "specific solubility." He proposes that advantage be taken of it in order to secure corroborative evidence in forensic blood identification work, as when positive it serves to prove the specificity of the reaction obtained. When dealing with very small amounts of the material to be tested, it may also be of value in enabling the specific diagnosis to be made with greater certainty than would be the case if only the ordinary precipitin reaction were available.

Deutsche medizinische Wochenschrift, February 21, 1907.

The Treatment of Hemorrhoids by Means of Injections of Carbolic Acid.—Franck is of the opinion that this operation has a sphere of usefulness in the work of the general practitioner in dealing with selected cases in which there is no local contraindication and in which general anesthesia is undesirable. He suggests the following modifications of the usual technique: The fluid injected is a 50 per cent. solution of carbolic acid in alcohol, but, before throwing it into the hemorrhoid, this is rendered tense by the application of a wire snare around its base. The loop of the instrument is tightened gradually, so as to cause the tumor to become congested slowly, and the needle is plunged directly into the center of the mass, and several drops of the carbolic acid are injected. The snare is not removed until the entire mass has undergone thrombosis. Each tumor is treated in this way, and a local dressing of drying powder is applied. On the fourth day a dose of castor oil is given, and by the seventh or eighth day the necrotic tissue has usually sloughed off. Complete healing requires from three to four weeks. The existence of deep fissures or large size of the hemorrhoidal masses constitute contraindications to the injection operation. The author lays especial stress on the use of the snare in order to produce congestion of the tumor and to restrict the amount of thrombosis, and on the employment of an alcoholic solution of the acid.

Diverticulum of the Esophagus.—Meisenburg states that, thanks to the introduction of the use of the esophagoscope, it is now possible to make the diagnosis of esophageal diverticulum with considerable accuracy. Starck, in his monograph, was able to collect records of ninety-three cases reported up to 1900, but since then the number of cases has been very largely increased. Lotheisen has described a special form of esophagoscope for use in such cases which is provided with a special lateral mirror intended to serve the purpose of affording a view of the opening into the pouch, but Meisenburg does not consider that this is necessary in order to recognize the condition. He gives the history of a case in which the presence of a diverticulum the size of a walnut was established simply by means of the ordinary gastric bougie, the operator finding it possible by suitable manipulation of the handle of the instrument to cause it to enter either the diverticulum or the lumen of the esophagus at will. The diagnosis was later confirmed, both by esophagoscopy and by radiography, and the author calls attention to the necessity for care in the use of the former method by describing a rather serious subcutaneous emphysema that was caused at one session with the patient through a slight laceration of the pharyngeal mucosa produced through a sudden change in the patient's position while the tube was being introduced.

French and Italian Journals.

Scleroderma Cured by Mercurial Treatment.—Pietro Chirone discusses the etiology and treatment of scleroderma, describing a case observed by him that was cured by mercurial treatment, the skin becoming soft and supple after having been for some years hard and contracted. The etiology is only incompletely known, it has seemed to result in some cases from rapid cooling of the body after extreme heat; from a prolonged sojourn in a damp place; from traumatism or violent emotions; from morbid conditions of the genital organs, and from disturbances of the menstrual function. It occurs most frequently between the ages of 25 and 38. There are three principal varieties: edematous scleroderma, scleroderma in plaques, and scleroderma of the extremities. These forms are not entirely independent of each other; they may be associated with one another, or with other similar affections, especially Reynaud's disease, symmetrical gangrene of the extremities, erithromelalgia, facial hemiatrophy, and vitiligo. Scleroderma begins in the skin and subcutaneous cellular tissue, after a period of indefinite symptoms, by a hypertrophy of the tissues accompanied by induration and increase or diminution of pigment. To this succeeds a cure of the condition, or a complete atrophy of the skin, which may extend to the periosteum and the bones. There are several theories as to the nature of the disease: the nervous theory, which admits a neuropathic condition and trophic alterations in the skin; the arterial, which depends on primary alterations of the vessels, that is, arteriosclerosis due to alcohol and syphilis; the dyscrasic theory, scrofula, syphilis, or chronic rheumatism being the determining cause, and the phlogistic theory, according to which it is essentially a chronic interstitial inflammation of the skin. According to others it is related to pathological alterations of the thyroid gland. Histologically it is found that the corneous layer of the skin is intact, the reticulum of Malpighi is the subject of an increase of pigment, and the derma and subcutaneous tissues show a hypertrophy of the connective tissues. There is an accumulation of lymphoid cells along the vessels and in the lymphatic spaces. The best remedy is mercurial treatment, with frictions of the ointment externally, and iodide of potassium internally.—*Giornale internazionale delle Scienze Mediche*, November 30, 1906.

Physiological Pulmonary Anthracosis of Intestinal Origin.—According to Calmette, Vansteenberghe, and Greyser, in spite of opinions to the contrary which have been held, it must be admitted that colored dust is absorbed by the digestive tube and can be carried by means of the lymph through the mesenteric ganglia to the lungs. It must also be admitted that the existence of a physiological, pulmonary anthracosis of intestinal origin cannot be contested; and it must also be admitted that this form of anthracosis is absolutely identical with that which is observed in smokers and in miners and should not be confused with anthracosis which is purely mechanical and of aerial origin.—*Gazette des Hôpitaux, Civils et Militaires*, December 18, 1906.

Permanence of Spirochæta Pallida in a Pigmentary Macule Left After a Syphilitic Papule.—A. Pisani tells of a case of hereditary syphilis in a baby of two and a half years of age, in which mercurial treatment had been carefully carried out, which had a macular lesion left after the atrophy of a syphilitic papule that had appeared a few months after birth. The child had on only two occasions given any symptom of syphilis, and had died of tuberculosis of the lungs, there being no syphilitic manifestations at the time of death. There were no microorganisms found in the internal organs, but the atrophied tissues in the left leg contained many spirochetes, while there were no traces left of the infiltration that had formerly existed. The spirochetes were diffused irregularly in the tissues; some were intracellular, some intercellular, some well preserved, others degenerated. The author concludes that in a patient properly treated by mercurials spirochetes are permanent in the atrophic residua of the specific papules even two years after apparent cure, and that in the latent periods of syphilis the spirochetes remain localized in the tissues which were the seat of previous manifestations.—*La Riforma Medica*, January 12, 1907.

Book Reviews.

American Practice of Surgery. A Complete System of the Science and Art of Surgery by Representative Surgeons of the United States and Canada. Editors: Joseph D. Bryant, M.D., Albert H. Buck, M.D., of New York City. Complete in eight volumes. Profusely illustrated. Volume II. New York: William Wood & Company, 1907.

The second volume of this system of surgery emphasizes the promise of the first volume that the completed work will make a surgical treatise without a superior in the literature of the world. The plan of the work confines the list of contributors to men of North America. Whether that is the best possible plan and one that offers a guarantee that nothing better could have been written is an open question. But it can be said without laying ourselves open to the charge of chauvinism, that, taken as a body, the surgeons of America are surpassed by none in the world. Many of the great and life-saving operations have originated in this country, and though the technique of certain procedures may have been refined by workers in other countries, American surgery to-day has no peer, at least no superior, anywhere in the world. A national work, furthermore, has the advantage of presenting the science of which it treats in the form recognized and followed by the leaders in one's own country; it is in accordance with the teachings of the country, and the views it inculcates are those held by the mass of practitioners. The contributors to this volume are all men who have proved themselves by their works and have won a national if not all an international reputation. They are: W. C. Borden of the U. S. Army, C. R. Darnall of the U. S. Army, C. N. Dowd of New York, V. P. Gibney of New York, A. F. Jonas of Omaha, E. L. Keyes, Jr., of New York, J. F. Leys of the U. S. Navy, W. McD. Mastin of Mobile, D. W. Montgomery of San Francisco, P. M. Pilcher of Brooklyn, J. C. Stewart of Minneapolis, B. T. Tilton of New York, D. F. Willard of Philadelphia, and A. C. Wood of Philadelphia. The subjects treated of in this volume are: "Diseases Which Belong in Varying Degrees to the Domain of Surgery (Leprosy, Plague, Glanders, Scurvy, etc.)," "Tuberculosis and Syphilis in Their Relation to Surgical Work," "Surgical Diseases of Widely Distributed Structures of the Body," "Surgical Diseases Caused by Heat, Cold, and the Electric Current," and "Simple and Complicated Wounds." Each one of these chapters deserves a special review, but the limits of the present notice forbid. The reviewer, if space permitted, would criticise some of the sections of some of these chapters as possibly lacking in the completeness looked for in an encyclopedic treatise, but he has no fault to find with the teaching, which is eminently orthodox. The get-up of the volume is all that could be desired. The book is heavy, indeed, but encyclopedias are not manuals and are not gotten out in pocket editions. The illustrations are numerous and explanatory, and we commend the wisdom of the publishers in not sacrificing the text to them. Where half-tone pictures have demanded it, moderately calendered paper has been used, but for the most part the paper is of a dull finish, which does not try the eyes, and the man with normal vision or one which has been made normal by glasses, will not pay for his study of the work, even by artificial light, with a racking headache.

Biographic Clinics. Volume IV. Essays Concerning the Influence of Visual Function, Pathologic and Physiologic, Upon the Health of Patients. By George M. Gould, M.D., Editor of *American Medicine;* Author of "An Illustrated Dictionary of Medicine," "The Practitioner's Medical Dictionary," "Borderland Studies," "The Meaning and Method of Life," etc. Philadelphia: P. Blakiston's Son & Co., 1906.

In this volume Dr. Gould reviews the life histories of Balzac, Tchaikovsky, Flaubert, Lafcadio Hearn, and Berlioz, extracting from their biographies and letters many references to morbid symptoms which the experience of many modern ophthalmologists teaches were due to eyestrain. The symptoms were similar to those of Carlyle and his wife, Huxley, Darwin, Spencer, Parker, Wagner, Nietzsche, and others, whose troubles were recounted in earlier volumes of this remarkable series—headache, vertigo, nausea, indigestion, abdominal pain, mental distress, wretchedness, in monotonous iteration, all due to, or at least explicable by, reflex disturbances from ocular defects, and all probably preventable by properly fitted spectacles. If Gould is right, and no one who has experienced the relief from recurring headaches and vertigo following the correction of visual defects by glasses can doubt that he is in the main correct, even if one hesitates to follow him to the limit of his contention, the tardiness which has characterized and still characterizes the acceptance of this truth cannot but be deplored and wondered at. The paper on Lafcadio Hearn is the most interesting of the series, though less instructive, since this writer's ocular defects were apparently irremediable. The interest of the chapter lies in the fact that the author and his subject enjoyed an intimate personal acquaintance, and Gould points out most entertainingly the influence upon Hearn's personal character and literary peculiarities of the extreme myopia and monocular vision from which this gifted creature suffered.

There are several other essays in this volume, not "biographic clinics," but bearing upon the question of eyestrain and its enormous importance in the etiology of functional disease. The first chapter is entitled "Progress" and deals with the evidence of the gradual acceptance of the doctrine of eyestrain by men of prominence in all branches of medical practice. Other essays are "The Cause, Nature, and Consequences of Eyestrain," "The Etiology of Astigmatism," "A Study of Failures in Ophthalmic Practice," "The 'Exaggeration' and Hobby-Riding of the Eyestrain Theorist," and "The Eyestrain Origin of Epilepsy." These articles are polemic, some of them extremely polemic, in tone and not calculated to convince those suffering from the theological disease of "invincible ignorance," especially those personally attacked. Dr. Gould is in discussion a hard hitter and he hits hard in these essays. It is a question, we think, whether the method he has chosen is the one which will win the most converts to his views; it certainly will not convert his active opponents—but probably nothing would. Those who are already half convinced and those who are open to conviction will read the book with interest, and if not converted will at least feel that they have been repaid for the time they have given to the reading.

Rhythmotherapy. A Discussion of the Physiologic Basis and Therapeutic Potency of Mechano-Vital Vibrations, etc. By Samuel S. Wallian, A.M., M.D., etc. Chicago: The Ouellette Press, 1906.

This is another form of treatment which is to be added to the large aggregation of physiological methods now in vogue, but it is apparently only a modification of what we have known for some time as "vibration." It is not to be denied that in this, as well as in many other methods of a similar character, there may be some value, but unfortunately the faith of the sensible reader must be shaken when in a book of this kind by an enthusiastic advocate of some particular "school" every disease in the calendar is brought under the benign and beneficent influence of the method exploited. Alopecia, anuria, appendicitis, ataxia, blenorrhea, bronchitis, and so on through the entire alphabetical list of diseases down to venereal affections and warts, are all cured or benefited by "rhythmotherapeutic" procedures, although in a number of these the writer acknowledges the value of other means of treatment. It may be that some day these methods will come to their own, but that day will be indefinitely prolonged unless the subjects are presented in a more rational manner.

Essentials of Human Physiology. By D. Noel Paton, M.D., B.Sc., F.R.C.P. Ed. Superintendent of the Research Laboratory of the Royal College of Physicians of Edinburgh. Lecturer on Physiology, School of Medicine of the Royal Colleges, Edinburgh. Examiner in Physiology in the University of Glasgow and for the Royal College of Physicians, Edinburgh; and Late Examiner in the University of Edinburgh. Second Edition, Revised and Enlarged. Chicago: W. T. Keener & Co.; Edinburgh and London: William Green & Son, 1905.

This handy volume contains all the physiology that is actually needed for the average student or practitioner of medicine who does not care to take up this branch as a special study. The author has kept the needs of the medical man in view, and has dwelt especially on the parts which have a direct bearing on the practice of medicine, relegating those of purely scientific interest to the background and treating of them only in so far as is necessary to a general comprehension of the subject. In the first part of the work the author treats of protoplasm, the cell, and the tissues, the latter being divided into the vegetative and the master (muscle and nerve) tissues. Following this are sections devoted to the senses and the nervous system. Part Second deals with the nutrition of the tissues, with subsections on the blood and lymph, the circulatory system, respiration, food and its digestion and utilization, internal secretions and immunity, and excretion. Reproduction is studied in Part Third. The author's style is clear and easy, making pleasant reading. Upwards of two hundred illustrations, mostly diagrammatic, serve to elucidate the text. The book is attractively gotten up, of convenient size and weight, and is completed with a very satisfactory index. Altogether the work can be confidently recommended to the student as well as to the practitioner who wishes to refresh his memory and to keep abreast of the advances in this interesting science.

Society Reports.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, Held February 25, 1907.

THE PRESIDENT, DR. WALTER LESTER CARR, IN THE CHAIR.

THE evening was devoted to a symposium on Fracture-Dislocations of the Spine.

Fracture-Dislocation of the Spine, Causation, Symptoms, and Diagnosis.—Dr. SAMUEL LLOYD read this paper. (See page 465.)

Pathological Changes.—Dr. PEARCE BAILEY read this paper. (See page 471.)

Surgical Treatment.—Dr. IRVING S. HAYNES read this paper. (See page 472.)

Dr. JOSEPH A. BLAKE said that he was more interested in the treatment of fracture-dislocations of the spine than in the diagnosis and the other features that had been presented by the readers of the papers. They were talking, of course, of fracture-dislocation of the spine, not the result of bullet wounds, or other fracture-dislocations which were apt to be associated with extensive cord lesions. In regard to the treatment he had taken rather a conservative ground. At Roosevelt Hospital they had a large number of cord injuries, but most of them were transferred. For the last two years he had taken the ground that operation should not be denied these patients; they should be given the opportunity of any benefit which might accrue from operation. Partial or complete lesions of the cord were always serious. In regard to fracture-dislocations of the spinal column without evidences of cord lesion, it seemed to him that it would be better to operate, to open up the canal, especially if the injury was in the upper part of the spinal column, and try manipulation and extension. The open operation, in his opinion, was better. All who had attempted the reduction of the fracture-dislocation without operation could appreciate how difficult reduction was, and how dangerous it was if the cord was not exposed and protected from injury. In complete division of the cord operation was not indicated. In partial lesion of the cord it could be divided into different categories; if there was a partial division with deformity, it was better to operate. When the patient presented evidences of compression it was better to operate. With regard to the time for operating operation should be performed before degenerative changes could take place, within the first day or two if possible. The time for operating was when the shock had subsided. Laminectomy *per se* was not a dangerous operation and did not injure the spinal column to any great extent, the integrity of the column being preserved.

Dr. JOSEPH B. BISSELL confined his remarks to the treatment of fracture-dislocations of the spine. He said it had been his good luck to have seen many acute fractures, mostly confined to the dorsal vertebræ, most of them having been elevator accidents, and he had not seen one case in which he did not think an exploratory laminectomy was indicated. Operation never did harm, and it might do good. Unfortunately his experience had not been large enough for him to draw any strong statements from the results. In all the cases that he had treated he said he would have been afraid to attempt restitution by manipulation; it was better by far to operate. If the cord was absolutely compressed or cut off, he advised that they should always prepare such patients for future troubles, that was, the occurrence of the persistent cystitis, and therefore do a suprapubic cystotomy and place in drainage.

Dr. WILLIAM B. PRITCHARD emphasized the importance of the last remarks of Dr. Bissell regarding the preparation of patients for troubles which were to come. The subject was not one which permitted a very extensive experience for any of them, but there were one or two impressions that had been deeply fixed in his mind. One was the extreme difficulty attending the making of an accurate diagnosis upon which to base a decision whether operative interference was indicated. The other question was one of prognosis. He believed the indications for operation were chiefly negative. The final outcome in the great majority of the cases, if operated upon, was extremely unsatisfactory; in cases of spontaneous repair, almost total disability resulted from fracture-dislocation of the spine with injury to the cord. When to operate could not be arbitrarily determined by any set rules. This was the matter of two factors, the personal equation, plus the experience of the specialized specialist in this particular field of medicine. It was on negative lines rather than on positive that cures had been accomplished.

Dr. WISNER R. TOWNSEND said that certain points had struck him in the handling of these cases of fracture-dislocations of the spine. In the first place there was the futility of any attempt at reduction by manipulation. It seemed to him unwise to attempt to reduce these cases, with or without an anesthetic, where one did not know how much compression there was. If any attempt was made it should be by the open operation. He had never attempted to reduce the deformity. He spoke of a patient seen in the hospital with a fracture-dislocation, and who was very comfortable in plaster. It was thought better to place some other form of dressing on. The dressing was applied, but not in the same way. When the patient sat up he became cyanosed and serious symptoms set in. It seemed to Dr. Townsend, in watching the work done in applying plaster-of-Paris, that not enough assistants were employed. The shoulder and body should be held, while other assistants hold the head. Dr. Townsend recalled a case of fracture-dislocation in the lower spine with symptoms of paralysis in which the jacket was placed on in a hammock, a safer method than by suspension. These jackets should be left on for a year or more.

Dr. WILLIAM M. LESZYNSKY said that his experience in fracture-dislocations was limited to the patients in the hospital and seen within a few hours, or within thirty-six hours. The most fatal cases were those that showed all the signs of complete injury to the cord and where the fracture-dislocation occured in the lumbar vertebræ. When the injury was in this region there was paraplegia, paralysis of the bladder, and rectum, and they were the most unfavorable cases. Yet when one considered the element of operation in these cases, and that laminectomy, particularly in the dorsal region, did not interfere with the integrity of the spinal column, the patient should be given the benefit of the doubt. He agreed with the statement that one could not determine positively within twenty-four or thirty-six hours that there was a complete severance of the cord. He saw a patient one year ago within two days after the injury. There were no positive findings of fracture-dislocation, yet there were evidences of compression of the cord, a hemi-lesion of the cord. At least there was a paralysis of motion on one side and of sensation on the other of the Brown-Sequard type. The canal was opened and a spicule of bone was found projecting from the body of the vertebra into the cord itself. This was rongeured off, the canal closed, but no improvement occurred in a week. There was a long-continued subsidence of the symptoms, but the paralysis remained the same at the end of six or seven weeks. When the patient left the hospital he was no worse. With his limited experience he had come to the belief that, where the abdominal muscles were involved, the cases resulted most unfavorably.

Dr. REGINALD H. SAYRE said he would like to draw the attention of the members to the necessity of keeping patients with fractured spines protected for a longer time than in fractures of other bones of the body. He had had two cases under observation where the diagnosis of fracture had been made in a different hospital; these patients

had been kept in bed for a time and then dismissed after the subsidence of the symptoms. Later on, as soon as they got on their feet again for any length of time, symptoms of paralysis in the upper extremities in both cases came on. Both of these were cases of fracture of the cervical spine, in one case, total; in the other, partial. The symptoms subsided after placing on support to the head and neck, which was continued for many months. The skiagraph confirmed the diagnosis of fracture through the body of the vertebra with anterior displacement in one of the fourth upon the fifth. The other case referred to was before the days of the radiograph, and, therefore, the diagnosis was not confirmed by the *x*-ray.

Dr. Samuel Lloyd agreed fully with the statement made regarding attempts at reduction in fracture-dislocation of the spine by means of manipulation; one was very liable to do much damage.

MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK

Stated Meeting, February 18, 1907.

The President, Dr. Thomas E. Satterthwaite, in the Chair.

Bill for the Creation of a Single Examining and Licensing Board for Medical Practitioners in New York State.—Dr. Reynold Webb Wilcox introduced the following resolutions, which were unanimously adopted:

Resolved, That the Medical Association of the Greater City of New York, at its stated meeting, held in New York City, February 18, 1907, declares that it earnestly favors New York State Senate bill No. 154 and Assembly bill No. 160, inasmuch as they provide for the creation of a single examining and licensing board for medical practitioners, thus obviating on the part of the State all distinctions between the several existing schools of medicine.

Resolved, That this association is opposed to the bill that has been introduced into the present Legislature, proposing to create a special "School of Osteopathy"; further, that it is opposed to the legislative creation of any special so-called "Schools of Medicine," believing that such legislation is of no advantage to the public.

Resolved, That the corresponding secretary is hereby directed to send copies of these resolutions to our State Senators and Assemblymen, to the Speaker of the House and to the chairman of the legislative committee of the Medical Society of the State of New York.

Mental and Functional Nervous Disease in General Practice.—Dr. William B. Noyes read this paper. He said that a discussion of mental and nervous disease from the more technical point of view started with eliminating those cases of purely nervous and hysterical people whose cases did not deserve a separate diagnosis, as their trouble was merely temperamental and symptomatic. Yet the general practitioner had to take some responsibility for these cases, even though he realized that self-control and common sense would cure them without a physician. The trend of recent medical literature emphasized that cases of pure neurasthenia and pure hysteria were being much more sharply defined, and as a matter of fact were much rarer than they were formerly considered. This was obvious to anyone who examined the records of his clinic or private practice of recent years. The reason was the cutting away of the relatively unimportant cases on the one hand and considering other cases, formerly classed as hysteria and neurasthenia, as psychoses. Just as modern internal medicine had made its greatest strides when working hand in hand with the chemist, and operative surgery when borrowing mechanical methods and principles from the workshop, and general pathology when it had learned to use the methods and researches of the biologist, so if one desired to get a clear and reasonable basis for the study of nervous and mental disease he must turn to the facts, the methods and the theories of normal psychology. The human mind might best be understood if we compared it to a boat, or to a man swimming in water. We saw part of the vessel or of the swimmer, and what we saw was the part above water. Then came the water line, and below was the submerged part. In the case of the human mind, what we termed the part above the water line was the conscious or objective mind. The part below the water line, which the individual himself and the superficial observer ignored, was what psychologists termed the unconscious, or subconscious, or subjective mind. A healthy average mind in a healthy body, especially in the years of maturity, managed to keep its water line in about the same place. Hereditary instincts, reflexes, habits, memories, and various organic sensations that seemed to be forgotten were below the water line, below the threshold of consciousness, and for the casual observer nonexistent. In contrast to these normal personalities, whose water line of consciousness did not vary to any great extent, there was a class of individuals who possessed what was popularly known as an "unstable nervous system." We might speak of them as a class in which the water line of consciousness was variable to a marked degree. In such individuals, if some definite physical condition like a toxemia, a strain, or a shock arose, the very personality seemed to change. The swimmer was half out of water; he was obviously fatiguing himself with every stroke. He suffered from innumerable disagreeable sensations that a healthy man was unconscious of. Our education from earliest infancy was directed toward making us ignore thousands of sense impressions until in our adult normal state we were completely oblivious and unconscious of them. These cropped out again in the class of individuals under discussion, in whom the mental activity and inhibition were relaxed, and as a result fatigue symptoms were sure to appear. The balance or poise of the personality was changed, and normal mental and physical life was hampered by the appearance of various new and usually unpleasant phases of personality and physical sensations. The strain could easily become too great to bear, and a complete physical breakdown might be the result. All these persons developed the habit of introspection and devoted themselves to a study of their new symptoms. Yet most of these symptoms, if analyzed, were merely a part of the subconscious mental and physical life. The fatigue symptoms were new, but their appearance was to be expected under the circumstances. This condition we called neurasthenia, or nervous prostration.

In the rest of his paper, and along these same lines, Dr. Noyes discussed hysteria and the type of cases in which the subconscious mind developed fixed ideas. Of these the obsessions or *idées fixes* on the one hand, mental ties in perfectly sane people, and paranoia on the other, with persistent delusions and failure of reason and judgment, were contrasted. Also another type of cases, not unusual in general practice, was that where the patients, after suffering from what one might easily call neurasthenia or hysteria, seemed to pass into a silly, half demented or confused condition. Cases of this class were labeled dementia præcox. A few years ago this seemed to be a fairly clean-cut diagnosis, and was supposed to indicate a condition of permanent insanity. The diagnosis was at present confusing, because the time limit had been removed; many of the patients improved, and little was left but the negativism and the primary demented condition.

The Early Diagnosis of Insanity.—By Dr. Arthur Conklin Brush of Brooklyn, N. Y. The author stated that although some marked phase or violent outbreak on the part of the patient was usually regarded by the friends as the beginning of an insanity, careful inquiry would reveal the fact that in the majority of cases the bursting of the storm had been preceded by a prodromal period lasting for months or years, and during which the importance

of the changes in the mental life of the patient had passed unrecognized. Thus the opportunity of correcting the abnormal mental tendencies or guarding against their consequences was lost. The early diagnosis of insanity was rendered difficult by the fact that there was no abstract difference between the sane and the insane mind; that there were no elements found in insanity which were not present in sanity; that there was no sharp dividing line between the two, and that our knowledge of insanity, with one exception, was purely clinical and rested on no substantial basis. As there was no abstract difference between the sane and the insane mind, the recognition of the latter was most easily made by a study of the former, and the changes in the healthy mechanism which formed the insane state. One must be able to exclude entirely the doctrine that the mind or soul was something apart from the body, and be able to regard the mind as simply the product of cerebral activity. The psychic development of man formed his personality or ego, and depended much on his age, education, station in life and environment, but not wholly so, for we inherited mental peculiarities just as we did physical ones, for the reason already cited, that the mind was the product of our physical brain. It was the derangement of this wonderful mechanism which constituted an insanity, for by insanity we meant a disease of the mind, and not a simple loss of the same. In the prodromal period the picture presented was often one of cerebral weakness, such as was found in ordinary neurasthenia. At first the patient often recognized his condition, and complained that he did not sleep well; that he was depressed and irritable; that he became easily fatigued mentally and was worried about himself. But soon this recognition of his condition was lost, and one difference was soon apparent which widely separated neurasthenia from an insanity, and that was that the neurasthenic recognized his true condition, while the insane patient did not. That fact had long been recognized and formed the basis of all our law relating to the questions concerning insanity. An insanity, from its onset, showed itself by a disturbance of the whole psychic mechanism, although it might be most marked and remain so in certain functions of the mind. While there was nothing found in insanity which was not found in sanity, and while all the changes described could and did occur at times to a slight degree in the normal mind, it was their permanency and exaggeration to a point which rendered the patient unable to jude as to the nature, quality, and consequences of his acts, and thus unable to adapt himself to his environment, which divided the sane from the insane mind.

Aural Affections in Relation to Mental Disturbances.—Dr. W. Sohier Bryant said that with respect to mental affections, aural diseases might be divided into six categories: 1. Cases of aural derangement which bore no relationship whatever to mental disturbances. 2. Cases of aural disease causing mental irritation and leading to psychical affections usually colored by the ear symptoms. 3. Disturbances of the ear, which acted as causes of general exhaustion and hastened the psychic symptoms. 4. Diseases of the ear, which progressed to loss of hearing, destroying the connection with the outside world and thus upsetting the mental equilibrium. 5. Hallucinations of hearing, which were the result of the combination of an ear affection with a psychopathic condition, and which were caused by the subjective sensation of a disturbed organ of hearing falling upon deranged higher centers. 6. Affections of the ear, which were secondary to the mental disturbance. The first group occurred alone. The remaining five groups might be found variously combined in any given case. After discussing in detail these various aural derangements and their possible bearing upon mental affections, Dr. Bryant said the result of his experience in the examination of the ears of the insane had convinced him that ear disease was much more prevalent among the insane than among the sane. In fact, it was the exception not to have some demonstrable functional disturbance of the ear. The author found it present in 90 per cent. of the insane examined. In many of these cases a history could be obtained which showed that the ear disease was in existence before the insanity appeared, and in others the condition of the ears was such that it must have antedated the mental disturbance. His summary of the subject was as follows: 1. Insanity was usually found in conjunction with aural diseases; in the majority the two affections were mutually dependent. 2. Hallucinations of hearing arose from tinnitus through the misinterpretation of aural stimuli under psychopathic conditions. 3. Cessation of the tinnitus could be expected to relieve the auditory hallucinations.

In connection with his paper, Dr. Bryant presented a patient who was subject to distinct auditory hallucinations. The ear condition in this case was a moderate tinnitus, associated with slight deafness and catarrhal otitis, and a very marked degree of engorgement of the nasal mucous membrane.

Phototherapy in Nervous Diseases.—By Dr. A. D. Rockwell. (See page 474.)

Dr. William M. Leszynsky said that while most of the speakers had given quite a clear conception of certain nervous diseases in a general way as they appeared from the standpoint of the neurologist, very little had been said as to how such cases were to be managed. What could the general practitioner do for this class of patients after he had recognized them? How was he to manage a case of neurasthenia, or hysteria, or incipient or more advanced insanity? One of the first and most essential features in the treatment of such cases was change of environment. This was a difficult problem to face in dealing with patients who could not stand the expense, although steps had recently been taken in this city to provide a free hospital for nervous diseases.

Dr. Noyes, in closing, said that while there was ample provision in this city for the care of general medical or surgical cases, Bellevue Hospital and the Montefiore Home were the only institutions that took care of patients suffering from chronic nervous affections. The latter was a model institution and there was room for at least half a dozen similar ones in this city for the care of chronic nervous disease and incipient mental disorders. It is not impossible that private charities and church organizations did less satisfactory work in their hospitals for acute diseases than large municipal hospitals might do, but there was an enormous field for them in caring for chronic diseases, especially nervous and the less serious mental disorders.

Dr. Brush, in closing, said Dr. Bryant had sounded the keynote which he hoped would be followed in the treatment of the insane. Under the old method, the treatment of the insane consisted essentially in shutting them out from the world, but we now recognized the fact that these so-called hallucinations of the insane were really illusions resulting from faulty organs of the body, and one of these was the ear. If we could remove the cause of the insanity before the mind was hopelessly broken down, we would do much toward restoring the patient to a normal mental state.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON PUBLIC HEALTH.

Stated Meeting, Held March 12, 1907.

Dr. John S. Billings, Jr., in the Chair.

Milk as a Carrier of Infection.—Dr. Charles Harrington, secretary of the Massachusetts State Board of Health, discussed the transmission of the nonbovine diseases especially. These were chiefly typhoid fever, diphtheria, a group of diarrheal diseases which we usually called cholera infantum, and scarlet fever. In Massachusetts he had had

occasion to study eighteen small epidemics of typhoid fever, in fourteen of which the probable vehicle of infection was the milk; in three it was private or semi-public water supply, and in one instance it was unknown. Out of the fourteen traced to milk, they had been able in eleven instances to obtain a history of typhoid fever at the place of the milk production. Typhoid infection of the milk was relatively easily brought about. Out of 1,500 cases studied all over the world, investigators had found typhoid bacilli in the urine in about 25 per cent. About 4 per cent. of typhoid cases became chronic bacilli carriers. The speaker enumerated a number of instances in which these bacilli carriers were the cause of infections long afterward. It certainly was out of the question at present to examine the people having to do with milk supplies so carefully that such bacilli carriers would be excluded. In addition to this there was the danger of infection by way of infected water supplies. It had been found that extremely diluted water could be drunk by some individuals without any harm whatever. They were immune. Hence the consumers of milk infected in this way could become infected and yet no typhoid fever be discoverable at the source of the milk supply. The speaker had seen a case of this kind in which the water was grossly contaminated from a nearby privy vault.

Milkborne diphtheria was much less prevalent. The bacilli were not, of course, excreted by the urine or feces, and the disease was not waterborne.

Milkborne scarlet fever was still open to question. Epidemics of this character had been described, but the evidence was far from convincing. He had himself observed such an epidemic recently. On one day in January there were 63 cases of scarlet fever reported in Boston and vicinity in a population of about 800,000. In the next five days there were 485 cases, so that the total epidemic when it had run its course embraced 717 cases. On investigation it was found that 84 per cent. of the cases were in families supplied by a single large milk company doing both a wholesale and a retail business. The milk came from 200 farms and all these were investigated, with negative results. So, also, were all the drivers and others. Finally the infection was traced to a man tending the huge mixing tanks, whose duty it was to taste all the milk to see whether it was sweet or not. For this purpose an ordinary spoon was dipped into can after can and never washed between the tastings. The man had a suspicious tongue and sore throat, and his sister was found at home with peeling of the skin.

But all of the above cases of milkborne disease were as nothing compared to the diseases in general due to the usual dirtiness of the milk. Dr. Harrington referred particularly to the diarrheal diseases of infancy. During the year 1905 the following deaths were recorded for the German cities having a population of over 15,000: In March there were 1,500 deaths, in April 1,600, in July 15,000, in August 16,000. This was the regular picture everywhere. The purchasing public held the key to the situation; it should be willing to pay a little more. And yet this had been found practically an insurmountable obstacle. It was unfair to the clean dairyman to allow dirty milk to be sold. There should be State and municipal regulation of dairies and kindred institutions.

Pasteurization: the Advantages and Disadvantages to the Consumer.—Dr. Rowland G. Freeman of New York City began by defining pasteurization, and at once distinguished between real pasteurization and commercial pasteurization. It certainly was difficult to obtain good raw milk; hence it was necessary to pasteurize it for infants' use. He claimed that the thermal death point of tubercle bacilli should be the minimum that could be regarded as safe. What the thermal death point was was still a matter of debate. He read a long list of authorities and the degree of heat given by each. These differed considerably. As a safe average he regarded 155° F. for twenty minutes sufficient. Commercial pasteurization was only 158° F. for fifteen seconds. This was worse than useless, for he had known milks to have a higher bacterial content after this "pasteurization" than before. The purpose of commercial pasteurization was only to enable the milk dealer to market an otherwise unsalable milk. He was opposed to commercial pasteurization, but believed strongly in the efficiency and applicability of home pasteurization.

Pasteurization: the Advantages and Disadvantages to the Municipality.—Dr. Joseph Roby, Deputy Health Officer of Rochester, N. Y., said that there was one phase of the subject that he would merely mention without entering into any discussion, namely, the advisability of municipal ownership of the pasteurizing plant. It was a political question and not suited for a debate of this kind. The so-called commercial pasteurization, *i.e.*, 155° for a few seconds, he was absolutely against. True, pasteurization deserved some consideration. It would not in any way reduce the cost of inspection to the city. In fact, the milk supply should have more and more expert supervision. He did not believe in standardizing a milk by mixing it all together and so getting a 4 per cent. cream. It would be better to be satisfied with it as it ran, some days high, some days low. The newspapers and others should be taught to discriminate between "adulteration" of milk and a milk merely below standard. He did not think that the milkborne diseases amounted to much. The epidemics were quite rare. Intelligent supervision could do a great deal here. The farmer should be instructed as to the danger to the milk supply from any diphtheria, scarlet fever, typhoid and the like on his premises. The significance of a sore throat should be pointed out to him. Pasteurization, he thought, would tend to make the milkmen careless. They would use any old milk. The heating also caused changes in the milk which made it less digestible. He had described a scheme some time ago which would largely do away with the evils complained of. It was merely the substitution of a modified can for the milking pail. The can held twenty quarts, was supplied with a slit through which the farmer milked (through cheese cloth), and the whole outfit was sterilized at the central creamery or dairy and delivered sterile to the farmer. The latter milked into it without any previous rinsing. If such a can of milk were quickly cooled and then shipped—preferably without standardizing the milk by mixing in a vat—it would have a very low bacterial content by the time it reached the consumer. He believed that if pasteurization were adopted it should be of such a character that tubercle bacilli were killed. The best remedy of this tuberculosis problem he saw in the immunization of cows as practised by von Behring. In this way, with the milk given raw, the infants would be fed with a milk rich in antibodies against tuberculosis.

Current Misstatements and Fallacies Regarding the Milk and Milk Supply of New York City.—Dr. William H. Park of New York City began by calling attention to a number of misstatements and inaccuracies which appeared chiefly in the lay press, but also in some of the medical journals. Many of the writers seemed to think it was thoroughly justifiable to exaggerate, so long as they were doing it in a good cause. According to some, all of the contagious diseases were to be largely wiped out. As a matter of fact, we should not expect any such thing. Only a very small proportion of these were milkborne. Then, too, it should be remembered that the diphtheria bacillus does not increase in the milk at the ordinary temperature at which milk is handled. The tubercle bacillus does not grow in milk at all—at any temperature. And yet many authors spoke as though these bacilli were commonly found and increased enormously in milk. It had been stated that a large number of the cows in New York State were tuberculous. This was probably true, though the figures are perhaps nearer 10 per cent. It had also been stated that the milk sold in New York City was full of tubercle bacilli.

This was decidedly not true. Careful experiments both here and abroad had shown that in cows free from manifest tuberculosis, but reacting to tuberculin, the milk from the udders did not contain tubercle bacilli. It might become infected if the animal or another in the stall had clinical lesions, for then the bacilli were often abundantly discharged in the feces. In the case of cows having tuberculosis of the udder the milk of course was usually infected. But only about 1 per cent., or even less, of the cows had udder tuberculosis. Finally, it was still a moot point whether much tuberculosis is due to bovine infection. Certainly everything tended to show that direct infection, from person to person, was by far the more common method. Of the various disease germs which did get into milk, the typhoid bacillus was the one which would grow. Even this, however, grew but slowly at the temperature at which milk was ordinarily kept. This germ was easily killed by pasteurization.

Dr. Park then discussed commercial pasteurization. It was not a fraud, as some had said. We had no right to limit this term to five to fifteen seconds' heating. But he felt sure most of the opponents of this method had not made actual bacteriological tests, for it was surprising to see how great a destruction was effected by even very short exposures to 140° or 150° F. He had had set up in the Research Laboratory a pasteurizing apparatus of the type used commercially and had tested numerous samples of milk at various temperatures. A thirty-second exposure at a temperature of about 150° would kill most bacteria. It had been contended that in a pasteurized milk the germs developed more readily than in an unheated milk. The facts did not bear this statement out. Thus he had heated some milk containing 300,000 bacteria per c.c. for thirty seconds to 140° F. Tests made after heating showed only about 2,500 germs per c.c. After cooling, the milk had been kept in the icebox for twenty-four hours. Plates then made showed only 2,600 germs per c.c. In other words, no change had taken place. Several specimens had been infected with typhoid germs. Thus before heating the milk contained 1,500,000 typhoid bacilli; it was then heated to 140° F. for thirty seconds; result, 36,000 per c.c. In one minute there were only 0,000 per c.c. and in two minutes no germs at all. When a temperature of 150° F. was used all the typhoid germs were killed in thirty seconds. Experiments with diphtheria bacilli showed complete destruction in half a minute at 140° F. The speaker knew, of course, that this would not kill all tubercle bacilli. Many of these were killed, however, and experiments had shown that the others were injured. It certainly was worth something to kill all the typhoid, diphtheria, dysentery, and other similar disease germs and kill a large percentage of the tubercle bacilli. Practical results had always to be borne in mind. It was not necessary to heat the milk so that every tubercle bacillus possible in the fluid would positively be killed. Proper commercial pasteurization had distinct advantages in certain directions. He certainly did not think all milk should be pasteurized.

Dr. L. Emmett Holt, in discussing the papers, emphasized the fact that milk was not the largest source of contagious diseases in childhood. He believed that but little tuberculosis was brought about in that way. He believed in pasteurization, but warned against expecting too much from its adoption. Most mothers in the tenements already knew of the advantage of heating milk for infant feeding.

Dr. Lindsley R. Williams cited Japan as having just as much tuberculosis as we have in this country, and yet they use but very little milk there. We should educate the people to appreciate what a pure milk is really worth. Too much should not be attempted by legislation. Many of our laws were dead letters. We could not do everything by pasteurization alone, nor by inspection alone. Both would probably aid us in our work of preventing disease.

Dr. Simon Baruch said that nineteen years ago he had presented to the Pediatric Section of the Academy "A Clinical Study on the Etiology and Treatment of the Summer Diarrhea of Infants," in which the statement was made that sterilization of cows' milk must and would be a valuable preventive of summer diarrhea of infants. A retrospect of forty years enabled him to compare the fatality of the first half of that period, during which nearly every weaned baby fell victim to diarrhea in the summer—most of them succumbing, with the last half, during which he had never been called upon as a family physician to sign a single death certificate for infantile diarrhea, although infants formed a large part of his clientèle. Scrupulous sterilization of milk had wrought the magic change. This was his warrant for raising a note of warning against a return to raw milk as a food for infants. The portentous difference between human milk and cows' milk was that in the one case the milk passed directly from its source to the mouth of the infant, while in the other the milk was liable not only to generate its own bacterium lactis, which was so fatal to infants, but to become infected with other pathogenic bacteria on its more or less prolonged way from the udder to the consumer's mouth. Sterlization or pasteurization of milk was absolutely inefficient unless it were done in well stoppered bottles, to which no aerial contamination could have access. Sterilization in bulk of the milk supply of a city must prove fallacious and impracticable, and equally fallacious was the idea that the milk supply could be kept pure by official inspection. While the speaker regarded official milk inspection as a distinct advance in sanitation, he nevertheless held that all milk for infants should be pasteurized and all milk for adults should be boiled, unless its source was an officially certified dairy.

The Williamsburg Medical Society.

At a stated meeting, held February 13, 1907, Dr. Joseph Merzbach read a paper on the "Early Diagnosis of Carcinoma of the Stomach." He referred to four reasons which made cancer of the stomach occupy the most important position among the malignant diseases of the gastrointestinal organs. Cancer of the stomach comprised 41 per cent. of all cases of malignant disease. It destroyed life more rapidly than any other tumor, excepting cancer of the esophagus, on account of its own destructive effects and its deleterious influence on digestion. It readily produced metastasis. Its diagnosis was difficult and its surgical removal involved technical difficulties. The diagnosis depended on the history, subjective signs and objective findings. A sudden beginning of digestive difficulties in an individual advanced in life whose digestion had been previously good suggested the possibility of malignant growth and imposed care in subsequent examination. Suspicion was further justified if the appetite progressively decreased and was uninfluenced by proper treatment. Preservation of the normal appetite was observed only in instances in which the malignant process developed on the basis of a former ulcer. Sensations of fullness and pressure after eating had nothing characteristic, but eructations having the taste of food taken some time before and of a foul odor were signs of more weight. Pain was of little diagnostic importance unless it occurred spontaneously in a location where ulcers were not as a rule found, or if it was closely connected with or followed deglutition and was localized at the end of the sternum, suggesting cancer of the cardiac orifice. Vomiting of food long since ingested was an important symptom, taken in connection with others. Also important were small hemorrhages, but the characteristic coffee-ground material could not be expected for an early diagnosis. The speaker referred to the value of Falk's benzidin test, which could detect blood in the stomach washings even if present in a dilution of 1-200,000. Of the objective signs, anemia had a stronger claim for recognition among the early signs than cachexia. Enlargement

of the left supraclavicular glands was found in a small percentage of cases. Palpation revealed the seat of tenderness on pressure and the presence of a tumor, which, however, was not to be included among the early signs of this affliction. A tumor that could be palpated had already passed the stage when the radical operation was feasible. Pain on percussion at the ensiform cartilage indicated the possibility of some pathological condition at the cardiac orifice of the stomach. The test meal was the most important step in the objective examination. Since impaired motility and stagnation were comparatively early signs of carcinoma, except in the fundus, an empty stomach on the morning following a substantial meal argued against the existence of a malignant growth. The presence of pus, blood, or mucus collectively or individually, were very suggestive. This was particularly true of pus. In the examination of the test meal the points of great importance, when considered collectively, were absence of free HCl, decrease or disappearance of pepsin and rennet ferment, presence of lactic acid bacilli in angular configuration, the presence of amebas and spores. The speaker alluded to the method devised by Solomon for the examination of the stomach contents for albumin. Another recent method was Holzknecht's radiographic examination of the stomach.

Dr. John Osborn Palak read a paper on "The Treatment of Inevitable and Incomplete Abortion." He discussed three cases of abortion occurring before the beginning of the fourth month. The signs of inevitable abortion were rhythmical uterine pains, associated with sacralgia and pelvic tenesmus, chilliness or chills, nausea or occasional vomiting, and vaginal hemorrhage. By means of pelvic examination it was necessary to exclude ectopic pregnancy. Examination revealed increasing uterine contractions, the uterus was hard or alternately hard and soft, and the cervix was soft, open, or dilating, and the ovum protruding. During the first three months the ovum was usually expelled as a whole or broken up, with more or less hemorrhage. The management of inevitable abortion included the control of hemorrhage, the avoidance of sepsis, the complete evacuation of the uterus, and its proper retraction and involution. The speaker followed the plan of administering a quarter of a grain of morphine hypodermatically, and after thorough cleansing of the parts about the vagina, packing the cervix and vagina, with the patient in the Sims, or knee-chest position. This controlled the hemorrhage and completed the separation of the ovum. The tampon was left in position for at least twelve hours, after which it was to be removed and the uterine contents evacuated by the forceps, finger, or curette. Before the third month the curette was best; after the third month the aseptic finger was best. The uterus was never to be packed after it had been emptied, except for hemorrhage. A firm vaginal tampon was left in for twenty-four hours. An incomplete abortion was recognized by the bloody discharge, sepsis or failure of involution, as instanced by the soft, buggy uterus, the patulous cervix, and the detection of fragments of the ovum. The treatment was prompt aseptic emptying of the uterus, in order to avoid hemorrhage, sepsis, and adnexal inflammations. If the cervix admitted the finger, the patient was placed in the dorsal position, and after thorough disinfection of the parts the patient being anesthetized, the operator explored the uterus with the finger and any portion of retained placenta or other fetal remains was loosened and removed. The instrumental evacuation was safer in the hands of the skilled pelvic surgeon and in hospital practice. If the cervix did not admit the finger, it had to be dilated, and the uterus was then explored with the dull curette, and the contents washed out with sterile salt solution. If pieces of adherent placenta or membranes could not be removed with the finger, forceps, or curette, it was necessary to pack the uterus with strips of iodoform gauze, to administer ergot, and after twenty-four hours to remove the packing and the detached placenta. The after-treatment of abortions was important. It took longer to complete involution than after labor at term. Rest in bed for ten or twelve days was imperative. Douches were not to be given before the end of the first week, and then a douche of sterile water at 120° F. twice daily, preferably with a Davidson syringe. Following the douche the patient was to assume the knee-elbow position, to allow the uterus to rise out of the pelvis and to deplete the venous plexuses of the broad ligament. If present, a retrodeviation had to be corrected.

Chicago Surgical Society.

At a meeting held February 1, 1907, Dr. Edward H. Ochsner reported two cases of multiple exostosis, one of which was an exostosis the size of a filbert, springing from the anterior surface of the right lamina of the second cervical vertebra and making pressure on the cord. He also reported one case of severe acne varioliformis of the face, arms, and neck, which had greatly improved by the use of a vaccine made from the bacilli and cocci found in the pustules, according to the directions laid down by Wright. Dr. Thor. Rothstein spoke of the symptoms the man with exostosis showed before he was operated on. Dr. Frederick A. Besley read a paper entitled "Rupture of the Urinary Bladder," in which he reported twenty-three cases and detailed some experiments. In the discussion of this paper, Dr. D. N. Eisendrath said his experience was limited to two cases, one of which Dr. Besley had reported. There was one point in connection with that case, a child, three years of age, which, he believed, substantiated a theory advanced as to the mechanism of rupture of the urmary bladder. The mechanism of rupture of the urinary bladder in children had been but little referred to in the literature. The child of three was brought into the hospital one week after the injury with an infiltration extending from the median line back to about the level of the axilla, and from the pubes to the costal arch. A diagnosis of retroperitoneal rupture was made by exclusion, as he thought there could be no other possibility of any subcutaneous infection having arisen after a fall of this kind. He did a laparotomy and found an extraperitoneal tear, but one which did not go through the mucous coat, so that there was a slow onset of symptoms, which could be explained by the mechanism of the rupture; that is, undoubtedly the muscular coat must have torn first and left the mucous coat intact. He doubted whether this could be the case until he had recalled reporting a similar experience. Dr. Eisendrath made some further remarks on fractures of the pelvis complicated by rupture of the urinary bladder. Dr. L. L. McArthur said the essayist stated that between seventeen and eighteen pounds was required to rupture a bladder. That might lead to error if the statement was not made more clearly and specifically. He asked him if he meant pounds to the square inch or not? A column of water, six feet high, by gravity, makes a pressure of 2.4 pounds to the square inch approximately. It had been his peculiar fortune to see a bladder rupture while the irrigator with which the bladder was being distended was held up at arm's length on one of the stands that would hold the irrigator probably at a height of about six feet. It was during an operation that Dr. Danforth of Chicago was making, and Dr. McArthur assisting. The bladder, on being exposed by suprapubic incision, was found so low as not to be reached readily. Desiring to raise the fundus of the bladder, the viscus was distended with sterile water. While he was waiting for the fundus of the bladder to come up into the wound, there was a sudden spurt of water; he stuck his finger down and checked the stream until the irrigator could be lowered, when it was found that a rupture of the bladder had occurred just at the point desired to be opened, so that without any difficulty his finger went into the bladder through the perforation. He mentioned a Vienna surgeon who succeeded in rup-

turing the bladder with twelve ounces of urine. Dr. Bayard Holmes had operated upon four cases of rupture of the urinary bladder, and only one lived. Dr. John E. Owens recalled a case of rupture of the urinary bladder from a fracture of the pelvis. The rupture was extraperitoneal in an otherwise healthy man. Cases of rupture of the urinary bladder were, in his judgment, rare. He had seen many cases of fracture of the pelvis, but this was the only case of rupture of the bladder he had seen. Dr. Besley, in closing the discussion, said there was a difference of opinion as to which coat was torn first in a rupture of the urinary bladder, whether the mucous or serous coat. He found in watching tears occur experimentally, as he did in cadavers, it was not always the same coat which was torn first. The relation was changeable. Occasionally the mucous coat would give way first, then the muscular, then the serous coat. In some cases the order would be the serous coat, the muscular, and then the mucous coat. As to the point brought out by Dr. McArthur concerning the amount of pressure necessary to rupture the bladder, he would say that the measuring apparatus used was the ordinary steam gauge, which measured pounds to the square inch, and it was on this basis the estimations were made. Dr. Bayard Holmes reported three cases: Syphilitic tumor of the testicle, syphilis of the liver, and tumor of the colon. Dr. L. L. McArthur reported a case of adenocarcinoma of the uterus in which he did a hysterectomy, the patient making a good recovery. He also presented a specimen of osteosarcoma of the lower extremity of the femur. In the discussion Dr. Carl Wagner reported a case of osteosarcoma similar in many respects to the one narrated by Dr. McArthur. Amputation at the hip joint was done; the man recovered from the operation and was well to-day. Dr. A. J. Ochsner reported a case of sarcoma which involved the lower end of the femur.

At a recent clinical meeting, held at Cook County Hospital, Chicago, Dr. Jacob Frank presented two cases showing Dollinger's method of extirpating the glands of the neck. He also reported a case of an old ununited intracapuslar fracture of the neck of the femur, which he treated without nailing or wiring, with subsequent excision. Dr. Thomas A. Davis showed a case of gunshot wound of the spinal column. He exhibited a man upon whom he did a modified Kraske operation, resecting the rectum after doing a colostomy. He showed a woman, seven months pregnant, who received a gunshot wound of the thorax. She aborted on the fifth day, but was now well. Dr. B. Brindley Eads exhibited two cases, one of rupture of the spleen upon which he had operated successfully, and one of exstrophy of the bladder in a child, five years of age. Dr. William E. Schroeder showed a case of fracture of the second and third lumbar vertebræ. He exhibited a patient who sustained a fracture of the patella twenty-three years ago, and who now had enormous exostoses developing from the periphery of the cartilaginous portion of the femur. The joint was full of fluid and had to be aspirated. Microscopic examination was negative. He showed a patient upon whom he operated for a sarcoma of the back about two years ago. Two months ago the tumor returned, and had now reached an enormous size. The tumor was of the small round-cell variety. Dr. A. E. Halstead exhibited a case of hypernephroma in which the initial symptom was a pathological fracture of the left femur. He showed a patient with a large fascial sarcoma of the left thigh; exhibited two cases of tabetic joint disease, and a case of arthritis deformans of the polyarticular recurrent type. He showed a case of Hodgkin's disease, and spoke of the differential diagnosis between that disease, lymphosarcoma, and tuberculous adenitis. Dr. C. E. Humiston exhibited a boy, nine years old, who fell, striking his knee, but not producing any abrasion of the skin. Later a pyemic abscess developed on the knee, which was opened, and the joint was drained by the Fenger method. Dr. D. N. Eisendrath showed a patient who had three epigastric hernias and one femoral hernia. He reported and showed cases of retrocecal appendicitis, intussusception, sarcoma of the humerus following an injury, and ununited fracture of the humerus, as well as cases of ascites and venous angioma. Dr. M. L. Harris exhibited a man who a year ago sustained a comminuted depressed fracture of the skull. He likewise showed a case of properitoneal lipoma.

Medical Items.

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine-Hospital Service, during the week ended March 15, 1907:

A NEW METHOD OF OPERATION FOR EPISPADIAS.*

By CARL BECK, M.D.,

NEW YORK.

PROFESSOR OF SURGERY IN THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL; VISITING SURGEON TO THE ST. MARK'S HOSPITAL AND THE GERMAN POLIKLINIK.

WHILE the technical difficulties of changing an epispadiac furrow into a urethral canal are moderate in the balanic type, the restoration in complete epispadias has always formed one of the most delicate problems of plastic surgery. The usual methods, among which Thiersch's is certainly the most brilliant in its conception, all show one great drawback, namely, the persistence of the incontinence of urine.

FIG. 1

This fact is not astonishing, if it is considered that practically the aim of these well known procedures is to cover the furrow with a skin flap. The new arrangement looks like a canal then, but it does not exercise a function of its own, nor does the operation provide for a lining consisting of mucous membrane.

In a recent case I have succeeded in avoiding these drawbacks by an operation performed in the following manner:

The patient, a boy of four years, suffered from incontinence, so that his clothes were constantly soiled with urine. On September 28, when I had the first chance to examine him, he showed an imperforate, cherry-like glans, which, by being slightly curved upwards, opposed itself against a projecting abdominal fold above. When the glans was pulled forward or downward, a short penis appeared, the upper portion of which showed total absence of a urethral canal. Instead, there was a broad furrow,

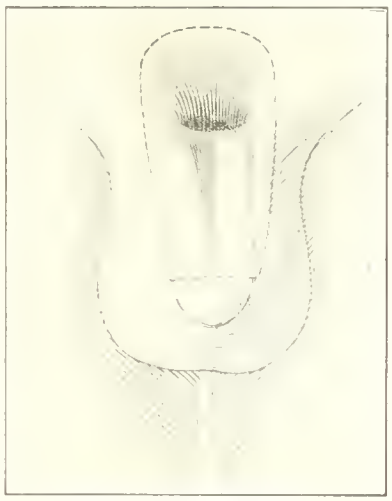

FIG. 2

lined with a thin mucous membrane, which continued into a large funnel-like orifice that permitted of the introduction of a finger into the bladder (Fig. 1). From this orifice slightly decomposed urine dribbled in short intervals. When the penis

FIG. 3

was left to itself the glans covered this opening like the cork on a bottle.

The funnel-like appearance of the orifice suggested to me to dissect the surrounding walls, including the whole urethral gutter, just the same as a hernial sac including the cord is liberated and mobilized in

*Case presented to the Surgical Section of the New York Academy of Medicine, November 2, 1906.

the radical operation for inguinal hernia. This plan was carried out by making a continuous incision around the funnel as well as the outer margins of the urethral gutter, the aim being then to shell out a coherent canal, which was meant to be the new urethra.

Fig. 4

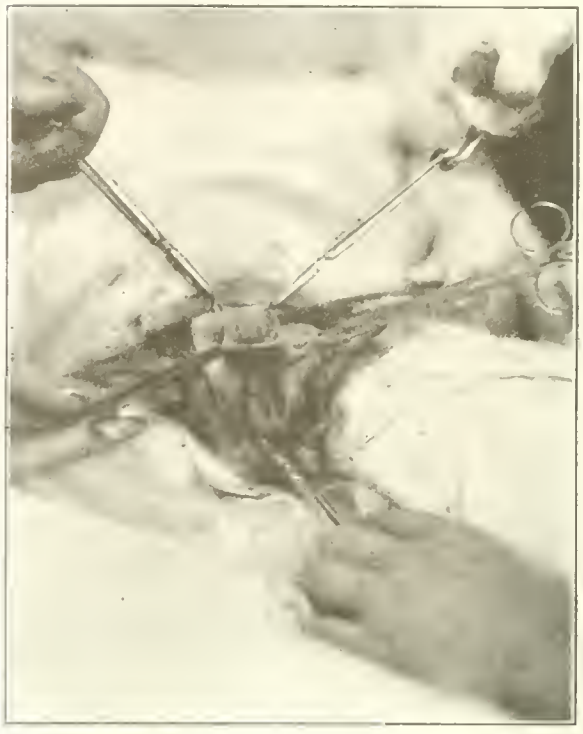

Fig.

First Step.—To secure sufficient material at the upper portion of this improvised tube, the skin incision was carried far up over the projecting abdominal fold (Fig. 2). The cicatrix-like outlines of the fold can be recognized in Fig. 3. In Fig. 4 the outlines of the roof of the new canal are indicated, the forceps on each side of the funnel lifting the slightly dissected wound-margins. The interior of the funnel being lined with a thin mucous membrane makes it especially useful for the purpose. To increase the size of the funnel, however, a small portion of skin was left at its upper portion like a brim. (Fig. 5.)

Now, further dissection was done cautiously by introducing the index finger into the orifice, pulling the wall over the finger as if trying to put on a glove, and then gradually freeing it from the surrounding tissues. The finger served as a guide during dissection, and at the same time drawing the funnel-wall over it caused enough pressure to prevent hemorrhage. Although the wall was naturally thin, it appeared to be firm, and, by holding the cutting edge of the scalpel more toward the outer tissues than to the wall, I avoided injuring any part of the funnel-wall. As soon as the upper portion of the funnel showed two inches in length, further dissection was stopped.

Second Step.—Now a transverse incision was made behind the glans which combined the two longitudinal incisions made alongside the urethral gutter at the beginning of the operation. Thus a flap containing the urethral gutter was created, which remained in close connection with the funnel, and practically formed an integral part of it after being freed as far as the interior of the original orifice. There was, in fact, now a new movable hollow

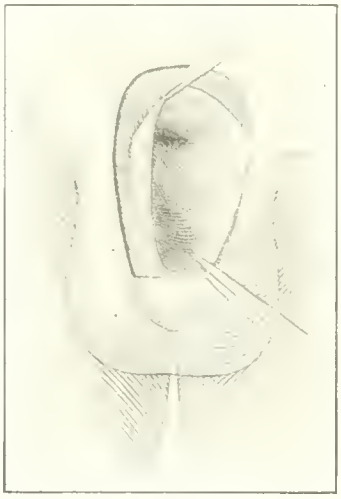

Fig. 5.

Fig. 7.

organ appearing like a hernial sac, at the bottom of which the neck of the bladder could be made out. (Fig. 6.)

To transform this wide tube into a urethral canal I folded its walls into several portions, pleating it like a shirt-frill.

Third Step.—Now, by perforating the glans with a bistouri I secured an opening which was wide enough to permit of pulling the upper portion of the sac through it, so that its ruffled margins could now be fastened to the tip of the glans after the principle of the purse-string suture (Fig. 7). They were supported by four silk sutures, one being applied anteriorly, another posteriorly, and another on each side.

In order to elongate the penis somewhat, I inserted a small triangular skin-flap between abdomen and penis, taking the material from the redundant foreskin.

The loss of blood during the operation was moderate. During the dissection of the funnel there was no hemorrhage to speak of. Only the mobilization of the urethral groove was followed by moderate

Fig. 8.

oozing, which was checked by hot irrigation and temporary pressure.

Recovery was uninterrupted. The patient complained of very little pain. During the first week he had no control of his urine. On the eighth day he could retain it for an hour, and in the third week for two to three hours. A few days ago he retained it for fully four hours. Now he can always pass some water on command. The fact that there is a stream of six inches in length after such a short period lets me hope that in the future more power will be developed.

It is true that the penis is still short. But it appears longer than it was, and it is brought into a normal position and direction (Fig. 8) instead of leaning against the abdominal wall as before the operation.

37 East Thirty-first Street.

The application of dry hot air to the thorax has been found very useful in cases of emphysema, chronic bronchitis, and bronchial asthma. The good effects are due to actively induced hyperemia of the chest-wall and coincident depletion of the lungs. The method is contraindicated in cases of advanced tuberculosis and cardiac insufficiency. —*International Journal of Therapy.*

PNEUMONIA, WITH ESPECIAL REFERENCE TO THE USE OF FRESH AIR AND A SALINE SOLUTION, AND THE ABUSE OF ALCOHOL, OPIUM, AND OTHER DRUGS IN ITS TREATMENT.

By STEPHEN SMITH BURT, A.M., M.D.,

NEW YORK,

PROFESSOR OF MEDICINE, NEW YORK POST-GRADUATE MEDICAL SCHOOL.

Since pneumonia continues to be one of the chief causes of mortality, and diversity of opinion still exists among physicians in regard to its treatment, repeated discussion of the subject should require no further justification. Those giving serious thought to the matter must perceive that, to find the source of an infection and the means for its prevention, is infinitely of more value to the human race than any system of medication. Limited numbers of individuals are restored to health by therapeutic measures; entire communities are saved from disease by wise sanitation. Pneumonia to a considerable extent is preventable, but so much depends upon personal initiative for its prevention that immediate prospects in this direction are not encouraging. Hence, we must persist in our endeavors to discover the best means of caring for whoever is visited by this Nemesis of indoor, sedentary, modern existence. It is a self-limited disease of short but variable duration—that is to say, a specific infection which, from the liability of its bacteria to perish, soon becomes exhausted—and ignorance of this fact leads to many therapeutic vagaries; disregard of it to endless differences about what are the effective remedies. The type of the disease, and likewise the outcome, largely depend upon the extent of the infection and the history of the patient. A majority of those with pneumonia in early life, and, indeed, at any time before the advent of degenerative changes, fortunately recover, whatever the method of treatment.

The best course to pursue with this affection, in my opinion, is to secure for the patient repose of mind and body, a simple regimen, and plenty of sunlight and outdoor air. We should maintain the strength, alleviate symptoms, and avert complications as far as possible, and, withal, promote the intrinsic capacity of the fluids and cellular elements of the body to overcome the virulence of the infection. Meanwhile, however, let us attempt nothing above all things that in any manner can injure this natural immunity. In a laudable desire to expedite recovery we are apt to lose sight of the evil results of over-medication. The recognition of symptoms and of complications, and the well-calculated giving or withholding of remedies will tax to their utmost the perspicacity and judgment of the attending physician. While many persons with pneumonia may recover without the use of drugs, a certain number will die, owing to various causes beyond our control, despite the most skillful management; but between these extremes there are numerous examples wherein the life of the patient depends upon the skill and resources of the medical attendant.

First in importance, according to my view, is an unlimited supply of fresh air to everyone, with few exceptions, suffering from this affection. The exceptions comprise a certain proportion of those with a terminal or a secondary pneumonia, and possibly some instances of idiosyncrasy, at least during inclement weather, where, perchance, there is not enough vitality to endure what, as a rule, is both bearable and beneficial. Reasoning from the good

effects of the outdoor care of pulmonary, as well as other kinds of tuberculosis, I came to the conclusion that for pneumonia a similar course had a like application. This has been my teaching for the past three or more years at the New York Post-Graduate Medical School, and likewise my practice whenever and wherever practicable. My conclusion, moreover, also was based upon the classic experiment of Alonzo Clark with typhus fever, which suggested its value in other infections. At one time, it is related, he had 250 cases of this disease in the wards of Bellevue Hospital. There were as many more and with a great mortality under the care of his colleagues. Though it was winter, the windows were removed, stoves were placed before the openings to warm the incoming air, and, except for some stimulants, no other medicine was given. Not one of Dr. Clark's 250 patients died, and in two weeks they were convalescent. Another such experience is recounted by Austin Flint,[1] which occurred as long ago as 1853 in the practice of Dr. John H. Griscom. Eighty-two patients with typhus fever were taken ashore from an emigrant ship at Perth Amboy, N. J. As there were no hospitals or other places of refuge, two shanties were built, boarded on three sides, over which old sails were stretched. Of these patients thus sheltered there were twelve insensible at the time of removal. The medical treatment consisted mainly of vegetable acids and bitters, and a liberal supply of cold water and of fresh air. All of the 82 recovered. In these open windows and half-closed shanties, allowing fresh air without stint, there was a lesson which it has taken us a long time to learn. We slowly have come to understand, however, that the outdoor air is a vital element in the treatment of tuberculosis, and it is my belief that, with little further delay regarding pneumonia, we may reach a like understanding. Meantime, an inborn prejudice in many of the laity, and in some of our profession, against this procedure will have to be overcome. Nearly every such innovation, however useful, has to fight its way into general recognition. No person in health takes cold while sleeping at night with wide open windows, whatever the temperature, if the head and the rest of the body are well protected. And, what is more, those who habitually sleep under these conditions store up enough energy during the night to enable them better to withstand the infections of the day to which they are commonly exposed in the devitalized air of the usually ill-ventilated, overheated places in which they congregate. The widespread fear of the outside night air probably was founded on a former ignorance of the manner in which it is now known malaria is acquired. It is the indoor air, day or night, too often shorn by the steam radiator of its life-sustaining properties, if not polluted by animal exhalations, that helps to undermine the constitution. We daily subject the face, and in breathing the lungs, to outdoor air at all seasons, and, if otherwise well protected, we do so ordinarily with impunity. Indeed, the entire surface can be made to bear, what our faces endure now, wintry weather practically unclothed. For instance, the savage Fuegians manage to survive, according to Darwin, in a cold, wretched climate almost entirely naked, and with little shelter of any description. At all events, during an illness like pneumonia, there is no danger of catching cold from simply breathing cold, fresh air. As a matter of fact, we do not catch colds; we catch infections; and there is much less likelihood of being infected out of doors than indoors. In the Arctic regions it is said, by the way, there are none of these diseases of the respiratory organs.

Let us place a patient, then, with this affection in a large, sunny room with wide open windows, if not actually upon a roof or a veranda, and thus continually supply the extra need of air caused by the toxemia and the consolidation. If the weather is cold so much the better, for cold air, especially when dry, excites respiration and thereby promotes oxidation. Moreover, it is more concentrated than warm air, and therefore contains more oxygen to a given inhalation. In some instances there may be an open grate fire, or any customary form of heat, to temper the air when there is small power of reaction. The patient must be kept comfortable by extra bed- and other clothing. Hot water bottles if necessary can be placed in the bed, and screens can be utilized for shelter from direct drafts. Two layers of coarse wire netting, between which are thin sheets of absorbent cotton, in the open windows, such as are in use in the Annex for the treatment of tuberculosis of the New York Post-Graduate Hospital, will filter the dust-laden air of a large city without hindering the desired ventilation. For toilet or other purposes that require the removal of covering, a person treated in this manner can be returned to a warm room, or the windows can be closed and the heat turned on temporarily. These conditions, in my opinion, afford the best means for ultimate convalescence. Pure cold air, especially when free from humidity, is soothing to a feverish and a delirious patient, and conducive to healthful rest and sleep; it promotes the appetite and improves digestion; it increases the strength of the heart and the tone of the arteries; it lessens the intensity of the fever and the frequency of the breathing; it adds to the bactericidal properties of the fluids of the body and of the cellular elements, and it stimulates elimination. The fresh air treatment of pneumonia has been tried with marked benefit in a hospital for children in England by a physician whose name unfortunately has escaped me, but who was, so far as I know, one of the first persons to publish his experiences. Nor am I alone in our country in my estimate of the value of this, with respect to the disease in question, somewhat recent departure. Northrup[2] says: "Fresh air stimulates the heart, reddens the blood, quiets restlessness, favors sleep, improves secretion and digestion; in short, meets most of the indications for treatment of pneumonia in infants." And what he so truly declares in the case of infants equally applies to adults. Likewise, Anders,[3] in his interesting article on the fresh air treatment of acute respiratory diseases, speaking of pneumonia, remarks that "Naturally, then, pure air is primarily an effective prophylactic agent against the immense majority of both acute and chronic respiratory affections." And in another paragraph he observes: "A personal acquaintance with the fresh air method, although somewhat limited, justifies the statement and belief that pneumonia patients are in no danger of contracting a cold from the perforation of the sick room with fresh air, and that the mere breathing of fresh air or the flowing of cool air over the face while the patient is confined to bed is practically unattended with risk in this respect." In concluding a valuable contribution upon this subject, Anders remarks, among other things, that the beneficial effects of the constant breathing of cool or cold fresh air are a lessened severity of the cough, and of the toxemia, and, withal, a better general condition than in cases treated by the more usual methods. In an article recently published by Thompson,[4] which every physician should read and consider, he says in regard to this subject: "The most striking benefit of the uncooked air treatment is shown in cases of pneumonia. Delirious alcoholic patients, with

profound cyanosis, when taken out of the general ward and placed at windows open day and night, became much less nervous and restless, and distinctly less cyanosed. I formerly gave such patients oxygen, sedatives, whiskey, and other stimulants. In the open air they, of course, receive no oxygen and require far less of stimulants and sedatives. During 1906 we treated in all, at the Presbyterian Hospital, 128 cases of acute lobar pneumonia. Of these patients, 47, or 36 7/10 per cent., received absolutely no drugs whatever—no stimulants, no narcotics, no inhalations, no specifics, nothing except the occasional laxative, which any one in bed with fever may require, and they all recovered, in the usual way, when the time came. Some defervesced by crisis, some by lysis, some in five days, some in twelve days, or other intervals. A large proportion of these patients received the uncooked air treatment and enjoyed it."

With regard to the diet, there is more danger of overfeeding than of any lack of nourishment. Considering that the gastrointestinal functions are deranged, it is only hurtful to add to the system extra burdens of digestion and assimilation. Small quantities of pure milk, either plain, diluted with vichy, or predigested, every two hours, possibly fortified now and then by the yolk of an egg, alternating with beef tea and various broths, such as barley broth in particular, is a regimen that has proved satisfactory. When a patient happens to be sleeping naturally, by the by, rather than disturb him, his food should be for the time being withheld. Water must not only be freely allowed, but also frequently urged upon the patient, for it should be kept in mind that milk is food, though fluid, and is adequate neither to quench thirst nor effectually to flush the system, an important proceeding when there is an additional poison in the body to be expelled.

A predisposing cause of pneumonia, it seems to me, is the intestinal autoinfection which prevails so extensively among the many overfed, poorly renovated, subjects of suboxidation. When the added toxemia of the diplococci has to be cared for by the natural filter of the body, the liver, as explained by Hutchinson,[5] this organ is in danger of giving out. Failure of this hepatic function in order of time precedes heart failure, and is almost of as serious moment. This increased load upon the liver should be relieved by diluents, diuretics, laxatives, and, may be, diaphoretics, and not by attempting a direct action upon that organ by the so-called cholagogues.

Without much doubt the fluids of the body, such as the serum and plasma of the blood, aside from the wandering cells, contain a substance capable of decreasing, if not destroying, the potency of pathogenic bacteria. Whether or not this substance, which has been christened "opsonin" by Wright[6] and Douglas (a word derived from *opsono*, I prepare the food for), and is considered by them an independent entity, is merely the product of the various phagocytes as held by Metchnikoff,[7] is somewhat immaterial. Upon the theory that this ingredient of the animal fluids aids phagocytosis, by a chemical union with the invading bacteria which inhibits their activity, Wright is making inoculations with special toxins manufactured from disease-producing germs designed to increase the immunity of human serum against infections. The method of arriving at the so-termed opsonic index of an individual, in order to regulate the strength of a dose, is rather complicated, and scarcely feasible beyond the reach of a well-equipped laboratory. However promising and interesting this, what is called opsonic therapy, may be, concerning pneumonia it requires further development.

Meantime, resistance to pathogenic microbes may be enhanced by injections, among other materials, of a physiological saline solution. Animals, such as guinea-pigs, thus treated, as shown by various observers, will resist doses of virus that always kill those used as a control. An infection like the one under consideration consumes the alkaline salts of the blood, and augments its density to a degree that impairs the functional activity of the living cells, and, meanwhile, the supply of these alkaline salts, if not the much-needed fluid, frequently is cut off by customary dietary restrictions. Hence the suggestion, first made by Henry,[8] of injecting a physiological saline solution in a patient with pneumonia to restore cellular, and also renal activity, has proved invaluable. In fact, the introducing of this solution under the skin, a procedure known as hypodermoclysis, has rescued a number of patients in my practice, as well as in that of many others, from impending dissolution. Care should be observed, it must be remembered, not to inject more than one dram of the solution to each pound of the body weight in each quarter of an hour, lest the tissues become injured by inundation. Such a procedure without doubt would be useful from the beginning in pneumonia. The administration by the mouth, however, of alkaline salts consisting of 10 grains of sodium chloride, 5 grains of potassium bicarbonate, and 1 dram of lemon juice, to 8 ounces of pure water every two hours, as recommended by Todd[9] in his instructive article on this subject, is constituted to accomplish, and with less trouble to all concerned, everything, except in certain emergencies, claimed for hypodermoclysis. It stimulates the function of the cellular elements, diminishes the density of the blood as shown by the decrease in the specific gravity of the urine, lessens the fever, and promotes elimination.

If pneumonia is attended by expectoration, which is not always the case, without fail the sputa should be destroyed, and, further, since the germs of the disease are voided by way of the bladder and the intestines, the urine and feces also should be destroyed.

An urgent symptom at the beginning of this disease is the pleuritic pain, though fortunately it is not always in evidence, and the remedy most frequently employed for its relief is a hypodermic injection of morphine. In truth, many physicians consider anywhere from an eighth to a half grain of this drug for that purpose useful and harmless, if not indispensable. To be sure, it is not likely to do so much harm at this stage, while the patient still has considerable power of resistance, as when the illness is more advanced, but any preparation of opium is always more or less baneful in its effects, if not dangerous, especially in old persons, young children, and those suffering from secondary pneumonia. Whence, inasmuch as this affection yet remains one of the chief causes of death in this part of the world, it would appear worth while to consider whether certain conventional ways of treatment may not contribute to this excessive mortality. It has been established by experiment that the ingestion of morbific bacteria by the living cells of the body is one, if not the only, means of deliverance from an infection. Therefore, this cellular function should be conserved if not promoted; certainly not injured or destroyed. Now, Metchnikoff[7] relates that Cantacuzene caused the death of some guinea-pigs, highly immunized with the cholera vibrio, by previously injecting them with small

quantities of the tincture of opium, which, as he was able to show, paralyzed the activity of the white blood corpuscles. Metchnikoff remarks, apropos of this experiment, that the phagocytes, although among the most resistant elements of the body, are not entirely proof against poisons, and that opiates and the like, which weaken phagocytic action, should carefully be avoided. Moreover, opium with its congeners, except in the minutest dose, depresses and finally paralyzes the breathing centers, and also checks every secretion save that of the integument. We know that the existence of a patient with pneumonia in great measure depends upon maintaining as far as possible respiration and elimination. Breathing 40 instead of 20 times a minute, the sufferer is trying by frequency to make up what is lacking in fullness of respiration. The kidneys, which are the chief means of excreting poisons from the system, to say the least are sluggish in pneumonia. Consequently, a drug that adds to the inactivity of these organs, and that tends to paralyze the living cells and the centers of respiration, in a malady such as this, must be injurious, if not actually hazardous.

If the pleuritic pain cannot be alleviated by such simple expedients as an ice bag, or a hot poultice, or else by strapping the affected side, the application of leeches, or, still better, of dry cups, will almost invariably prove efficacious. But dry cupping must be done thoroughly. Although it is desirable to relieve these pains, the means of relief never should be at the expense of a patient's power of resistance. Rather than imperil ultimate recovery, it would be better, if otherwise without remedy, to endure for a while some discomfort, or even suffering. Thus, only after all other resources have failed, and the distress is unbearable, should opium be used, even at this early stage of the disease. The one possible exception to this rule is when the patient is a victim of the opium habit, for then it may have to be allowed, though a forlorn hope, as an essential factor of the treatment. Preparations of opium likewise sometimes are given to arrest or to lessen the cough, which if annoying is not especially harmful. In fact, the average cough of pneumonia with expectoration, for obvious reasons, rather should be encouraged than suppressed. Further, these drugs are now and then prescribed in this disease to quiet restlessness, and nearly always, in my belief, to the patient's detriment, however comforting to his family and friends, for restlessness at this time is vastly preferable to a narcotic tranquility. A simple remedy such as sodium bromide, and even moderate doses of alcohol, are better than opiates for this condition. Cough and loss of rest and sleep, however, as previously stated, are not prominent features of the fresh-air treatment. That I am supported by good authority in my opinion of such remedies in this affection is shown by a small part of what Sir Wm. T. Gairdner,[10] formerly Professor of Medicine in the University of Glasgow, has to say in this connection, namely: "I regard opium as a drug of extreme danger in pneumonia. I am aware that men of great eminence have taught otherwise. But in so representing the case I am not advocating any theory, but rather am dealing with facts which I know to be true, and which, if true, are such as ought to be in the mind of every practitioner. I have repeatedly seen what can only be regarded as poisonous effects from very moderate doses of opium in certain stages of pneumonia; and (especially towards the crisis) have learned to dread it more than almost any other drug." Morgan[11] states that he has a great repugnance to the use of opium in pneumonia, and he is inclined to believe that many of his fatal cases owed their fatality to its injudicious employment. Finally, with experimental proof that even small doses of opium paralyze the activity of the white blood corpuscles, and clinical evidence that it is harmful in other specified ways, I feel warranted in saying that physicians should think seriously before resorting in this disease to its administration.

The rise of temperature, such as occurs in pneumonia, is not only an index and measure of the infection, but one of the ways in which nature checks its progress. In the minds of some physicians fever should be lowered at all hazards; whereas, short of well defined hyperpyrexia, which is exceptional, it should be let alone, since it is not harmful, but advantageous. High fever may tell of an extensive infection, also it reveals an efficient power of reaction. Moderate fever indicates either a slight infection, or else a deficient power of reaction, as often seen in secondary and terminal pneumonias. Lenhartz[12] teaches that pathogenic bacteria, such as the pneumococci, thrive best at the normal human bodily heat, and that they decrease in vigor with the onset of fever, and finally die, or at least lose their toxic properties. Bouchard[13] observes that certain microbes are known to perish at temperatures which human beings readily withstand. For example, the bacteria of malignant pustule are unable to exist above 104° F., and thus cannot infect birds whose normal heat exceeds this limit. In an interesting experiment, by the way, Pasteur,[13] having reduced the temperature of a bird artificially, was able to destroy this immunity. Increase of heat above 98.6° F. creates a physical medium that is inimical, if not destructive, to infectious organisms. Experiments show that what are high temperatures in man do not produce in animals extensive fatty degeneration, for Naunyan and Rosenthal (Bouchard[13]) were able to keep rabbits alive for weeks with temperatures ranging between 105.8° F. and 100.4° F. without serious consequences. Therefore, if the action of heat is the same on the human heart as upon that of a lower animal under like conditions, there cannot be much danger in the short-lived fever itself in pneumonia. Krehl[14] remarks that very high temperatures may be harmful in the same manner that a heat stroke is, but that in fevers they are uncommon. It is possible, he also says, that a rise of temperature may diminish the growth or the virulence of the microbes, and, so long as the elevation remains within bounds it is relatively harmless. The rapid pulse and respiration, the loss of appetite, and the possible degeneration of the organs, in so far as they are directly caused by the temperature, are not in themselves dangerous. Finally, an experiment of Riess, quoted by Bouchard,[13] shows that the lowering of the temperature to the normal, in animals with fever from infection, neither stays the disease nor prevents a fatal termination. The cold sponge bath generally is helpful in case of restlessness, and, at the same time, somewhat of a stimulant, but, as a rule, it is not so effective in pneumonia as in typhoid fever, or so often necessary, especially during the cold fresh-air treatment. At all events, none of the antipyretic drugs, synthetic or otherwise, should be given in this affection, for they are superfluous, if not deleterious. Quinine in particular should not be used in large doses, for its action on the white blood corpuscles, as related by Metchnikoff,[7] has been found, like opium, distinctly detrimental.

The condition of the heart is one of the vital questions in pneumonia. Cloudy swelling, due in great

part to the toxemia, is prone to disable this organ. Dilatation, too, may occur, especially of the right side, with stasis in the veins and edema of the lungs. If considerable these are serious complications. As stated by Todd,[9] the blood, gradually having been reduced in fluidity and deprived of alkaline salts, tends to precipitate its fibrin, owing to an increase of specific gravity. This and the accumulation, meantime, of toxins in the circulation finally bring on cardiac paralysis.

Pulmonary edema calls for energetic dry cupping as well as for thorough stimulation. Ammonia, strychnine, digitalis, and caffeine are valuable for this purpose, but, at least in large doses, they should be reserved for such emergencies, and not ordered as a matter of routine. Strychnine and digitalis are most effective hypodermically.

The integrity of the heart is best conserved in the end by not goading it from the beginning with stimulants simply because the patient has pneumonia. The stronger preparations of alcohol, such as brandy and whiskey, are seldom needed in this affection, even as sedatives and depressants, which they are in fact instead of stimulants. It is now pretty well established that alcohol produces little, if any, real stimulation. A popular belief prevails that alcohol increases muscular and nervous energy, whereas it simply benumbs the nerves and impairs muscular coordination. Patients with a previous history of chronic alcoholism are known to be deficient in recuperative power, and almost invariably to succumb to pneumonia. But it is not so well known that alcohol directly inhibits and finally destroys the activity of the phagocytes. Deleard[21] of the Pasteur Institute of Lille (Metchnikoff[7]) proved by a series of experiments that absorption of alcohol beyond question greatly interferes with the production of immunity against hydrophobia. Also, he found that rabbits which were given alcohol while being immunized against anthrax died of the disease, and that control animals, which were not given alcohol, without difficulty could be immunized. Moreover, these laboratory tests were confirmed by Abbot,[7] who showed that animals, if brought under the influence of alcohol, became more subject to the harmful effects of several microbes, such as the bacterium coli, the streptococci, and the staphylococci. Subsequently, Laitinen[7] performed numerous experiments of a like nature and with similar results. For example, sundry rabbits were given alcohol for several days in succession, and then each was injected through the skin with a small dose of the first vaccine of anthrax. Six of these so treated died after a more or less extended illness, and they all were found to have anthrax bacilli in their blood and organs; whereas of four control rabbits which received this same vaccine and no alcohol, but one died; the other three remained in perfect health. It is thought by some observers, however, that a single dose of alcohol by the mouth or hypodermically will increase the quantity of the antibodies and temporarily the bacteriolytic power of the blood. Still, in spite of this, alcohol ultimately has a harmful action on the phagocytes, which are the chief means of defence against infective microbes, as well as upon the nerves and the rest of the tissues, and should not be used to any great extent in the treatment of infectious diseases, and especially in pneumonia. Possibly the one exception to this rule may be a case of chronic alcoholism. Burney Yeo[15] says that the routine giving of alcohol in pneumonia, especially in the early stages, with the idea of preventing cardiac failure later, in his opinion, is a serious error. "Alcohol," he also says, "produces vasomotor paresis and causes dilatation of the vessels, and it must therefore aggravate or induce tendencies to vascular engorgement." Hay's[16] account of the influence of alcohol on the circulation, quoted from a report by Professor Sherrington, is as follows: "Its primary action is on the mucous membrane of the mouth, esophagus, and stomach, and in virtue of this action it undoubtedly acts reflexly as a cardiac stimulant. This stimulation is neither prolonged nor powerful. After the absorption alcohol exerts a specific action dilating the peripheral bloodvessels and lowering the blood pressure, thus tending to empty the arteries and to fill the veins. On the heart itself, directly, alcohol seems to have no effect at all; in large doses it enfeebles it." Also Hay says, "Alcohol has a toxic effect upon the protoplasm of the muscles of the heart in addition to that of the pyrexia and toxemia." In conclusion, he remarks, "The total action of alcohol on the heart being depressant it is futile to give it in cases of commencing cardiac failure with the idea that you are combating that failure by giving a specific cardiac stimulant."

Carbonate of creosote in pneumonia has many advocates, and among them Smith,[17] who writes of the benefits of the drug with enthusiasm. This remedy in doses varying from 10 to 40 minims every two hours, is prescribed with the idea that, if begun soon enough, it will render the exudation in the air cells a poor culture medium for diplococci. Claim is made that it will lessen the severity of the attack, cause the disease to end by lysis instead of by crisis, and decrease the mortality. Meantime, the smoky urine which it produces is of little matter, and there are no symptoms which are harmful or disagreeable. It is held, too, that this remedy prevents gastrointestinal fermentation; always a troublesome complication. The inhalation of vaporized creosote is recommended also by Smith,[18] as well as by Robinson,[19] on the theory that it will have a direct local effect inimical to the parasite. It seems to me, notwithstanding, that unlimited fresh, and, if possible, cold air is what is most needed in the lungs during the entire course of the infection. The short, sharp struggle which takes place between the invading germs and the phagocytes at the innermost threshold of the body leaves in its wake a more or less extensive exudation, but the most serious result of this encounter is the subsequent toxemia caused by the entrance of the prevailing diplococci into the systemic circulation. Here the contest continues and the chief reliance of the patient is upon the living cells, the serum and plasma of the blood, and the emunctories. All these are best stimulated and kept in activity by the constant breathing of cold, fresh air, and the taking of the alkaline salt solution.

Oxygen by inhalation may be of benefit if well diluted and given early in the attack, but, as a last resort, though it lessens the cyanosis and distress of the patient, it fails to keep him alive. However, this gas is seldom required during the open-air treatment. Chloroform is used likewise by a number of physicians, and favorable results are reported, but I am not one of its advocates.

Local applications to the chest in pneumonia, such as hot poultices of whatever composition, or flannel and oil silk jackets, are valueless so far as the disease itself is concerned. Cold, wet cloths, on the other hand, or preferably ice bags, are considered serviceable by many practitioners.

With respect to the use of the lancet in this affection little can be said as a result of experience by the medical men of this generation. Its former abuse gave rise to a reaction that possibly may have

gone too far in the opposite direction. While there are some instances of obstruction to the right side of the heart possibly requiring venesection, the chief danger to this organ is more often a parenchymatous degeneration which requires stimulation. However, with an extensive lesion of this nature there will not be much reserve power in the heart left for stimulation. In these days bleeding sometimes may be of advantage, but, as a rule, the average city patient needs all the blood in his body for future contingencies.

When arterial pressure is high in the beginning it should, in my judgment, be left alone if not lowered by some simple remedy, such as a laxative or perhaps a little alcohol. Aconite, veratrum viride, tartar emetic, and the like, are worse than useless; they are actually harmful; they depress the action of the heart, and thereby produce one of the things we desire to avoid, namely, internal capillary stagnation. If there is high arterial tension associated with arteriosclerosis, nitroglycerin is the remedy, but it is permissible only under these circumstances. Low arterial pressure with fairly normal heart sounds is mistaken now and then by a novice for cardiac weakness. The vasomotor centers of animals infected by the diplococci are paralyzed from the first in varying degrees, as shown by Krehl;[14] meantime, excited action of the heart for awhile overcomes the initial tendency to a fall in arterial pressure which, however, eventually takes place. There may be a sudden failure of circulation, due to dilatation of the large abdominal vessels without previous warning. When these splanchnic vessels are involved the resulting collapse needs prompt and energetic treatment. It is much like what happens in surgical shock, and the intravenous injection of one or two drams of the 1:1000 solution of adrenalin in a pint of physiological saline solution, as suggested by Hare[20] for such a happening, may chance to avert immediate dissolution under these analogous conditions.

With the loss of vasomotor tone chiefly in the smaller arteries, and weakness of the first sound of the heart at the apex, and of the second sound at the aortic cartilage, besides accentuation of the pulmonary second sound, a giving out of the entire heart is threatened, if not imminent, and stimulants are indicated. Aromatic spirit of ammonia, Hoffman's anodyne, ergot, caffeine, digitalis may be taken by the mouth, or, in still more pronounced symptoms, strychnine alone or with atropine in large doses hypodermically. Should marked cyanosis with distention of the veins, dyspnea, labored action of the heart, and weakness of the pulse supervene, together with signs of pulmonary edema, the manifest engorgement of the right side of the heart possibly may be relieved by venesection, but at this juncture a critical moment commonly has been reached where much is done in desperation and little accomplished.

ON LOCALIZATION IN MULTIPLE INTESTINAL OBSTRUCTION, WITH ILLUSTRATIVE CASE.*

By G. A. FRIEDMAN, M.D.,

NEW YORK.

ASSOCIATE TO THE MT. SINAI HOSPITAL DISPENSARY; VISITING PHYSICIAN TO THE METROPOLITAN HOSPITAL AND DISPENSARY.

EVERY clinician knows how difficult it is at times to determine whether or not a given case is one of obstruction of the intestines. It is universally recognized that the diagnosis of obstruction belongs to the most difficult in the pathology of internal diseases. How often has laparotomy, performed for symptoms of obstruction, led to disappointing findings at the time of the operation. As an example, we can point to the symptoms of obstruction simulated by hysteria or to a condition of paralytic ileus. On the other hand, a condition of obstruction is often revealed during an operation or on the autopsy table, when such was not in the least suspected before the operation or during the life of the patient.

In case a positive diagnosis of obstruction has been made, we are still by far not ready for a therapeutic interference with the condition, granting, of course, that we are not willing to act blindly or to force upon the surgeon an exploratory laparotomy, for it is clear that by the term "occlusion" or "obstruction" we have named only a symptom. It is accordingly necessary to designate the seat of such occlusion or obstruction, which of course may not always be possible if one does not count self-evident cases with classical symptoms. And when we have made a positive diagnosis of occlusion or obstruction naming as its seat the large or small intestine, there may yet arise the question whether a second part of the gut may not be affected by a similar condition, the answer to which is of the utmost importance to the operating surgeon. Cases have already been recorded in which the symptoms of obstruction persisted after a laparotomy, so that a second

*Read before the Eastern Medical Society of New York.

operation was made necessary for the detection of the additional seat of obstruction. Even when these difficulties have been overcome there still remains the third question of the exact pathological condition leading to the symptoms of obstruction, and finally the problem of how to deal with any given case, whether to treat the patient medically in a conservative manner, or to resort immediately to surgical interference. The latter, moreover, is easier to decide in acute cases than in those that run a subacute or chronic course.

Our case is especially interesting because all the conditions for an exact diagnosis appeared one by one during the time of observation; the obstructions at two places were pointed out, the pathological conditions were precisely named, and surgical interference was insisted upon. The surgeon will be in position to communicate to you how useless would have been further palliative treatment which might have led to irreparable and disastrous consequences; the adhesions would have only increased in number, the intestinal coils would have become more closely pasted together, thus lengthening the time of a later laparotomy and narcosis, and reducing very much the chances for recovery of the little patient. Moreover, a subacute ileus could suddenly have developed into an acute condition, and thus led to a most deplorable result.

Boas, with reference to the difficulty of making the diagnosis in such cases, states the following: "Of all varieties of occlusion of the intestines this particular variety is the most interesting from the scientific, most frequent from the practical standpoint, yet most unsatisfactory from the standpoint of diagnosis." He continues in another place: "One is exposed to unavoidable mistakes in those rarer cases of simultaneous obstruction of the small and the large intestine, which Treves has described in his monograph, and to which Hochenegg has called attention more recently. In these cases of "combination ileus" one must be prepared to find multiple invaginations, cicatricial strictures, peritoneal adhesions, conditions of volvulus, all of which eventualities are of course beyond the possibility of diagnosis.*

Before we enter any further upon the reasons which enabled us to arrive at the diagnosis in our case, we want to state the patient's history.

David Fuchs, two years and ten months old, was brought to my office by his father on October 28, 1906. The father stated that the child was in perfect health until September 22: on that day it was struck by an express wagon, but was not run over. The patient was much frightened and was brought home fully conscious. That night it vomited once, the vomitus consisting of undigested food that had no fecal odor whatever. For the eight days following the child was perfectly normal. On September 30 violent pain set in in the abdominal cavity, as well as vomiting and constipation, yet without a trace of fever. In a few days a marked swelling of the abdomen was superimposed upon these symptoms. After ten days (on October 8), completely normal stools were reestablished, the swelling of the abdomen receded partially, yet the continuous pain and the vomiting showed no tendency to cease. Upon the advice of the attending physician the child was taken on the eleventh day of his illness to a hospital. According to the father, the child, during his stay in the hospital, did not vomit at all, had no pain, no constipation, and was therefore discharged after twelve days. For the six days following the child felt perfectly well, but in the three days preceding our first examination he had violent pain with and without vomiting each evening. Constipation and fever were absent. The father could not attribute the aggravation of the trouble at home to any gross indiscretion in diet, the old symptoms reappearing although the same semisolid diet was continued. The child was said to have lost much weight since September 22, having been a well nourished, robust child before the accident; he was said to have begun walking at eleven months and had not passed through any acute infectious disease in his infancy. Syphilis was likewise denied.

*Boas: Krankheiten des Darms, 1901, page 442.

Status Præsens:—First Examination (October 28). The patient possessed a well developd bony frame, rather weak muscles, and a much reduced panniculus adiposus. The visible mucous membranes were quite anemic, the belly was very much swollen, and the abdominal veins very prominent in the shape of a caput medusæ. Palpation from the umbilicus to the various abdominal regions disclosed no tenderness on superficial or deep pressure. The child continued to moan just as before the examination, apparently from fright. The lower border of the liver and the spleen were not palpable nor could a sensation of resistance be disclosed anywhere in the belly by a most thorough palpation. The existence of freely movable fluid in the dependent parts of the cavity was easily perceived. Percussion gave loud tympanitic sound all over, showing the existence of diffuse meteorism. Liver dullness could not be found because of this condition. Auscultation revealed the presence of widely distributed gurgling sounds and borborygmi. Examination with reference to a possible appendicitis was negative—McBurney's point not tender—rectal examination also was negative. There was no evidence of hernia; both testicles could be felt in the scrotum, and the rectal temperature was 98°. The organs of respiration and circulation were normal, the pulse was 100, easily compressible but regular. The examination of the urine gave the following data: The color was light yellow, reaction strongly acid, no albumin, no sugar, diazo test negative, no casts, and only a few squamous epithelial cells. Indican was in excess.

The child was kept in the office for one hour, with abdomen bared, in the hope that an attack of pain might intervene. This, however, did not occur. What could have been the diagnosis on this examination and what advice could we offer to the child's father? If we summarize the data obtained we have the following:

A. History:—(1) Trauma. (2) Vomiting—nonfecal—once in the night following injury. (3) Absence of any symptoms for eight days with absolute good health. (4) An illness of ten days' duration with continual violent pain, frequent nonfecal vomiting (four or five times per day), obstinate constipation. (5) Again cessation of all symptoms for eighteen days (twelve days in the hospital and six days at home). (6) Paroxysmal pain of three days' duration with and without vomiting. (7) Absence of fever throughout.

B. Physical Examination:—(1) Absence of tenderness in the abdomen. (2) Freely movable fluid in the peritoneal cavity absolutely shown. (3) Diffuse meteorism. (4) Well distributed borborygmi, and (5) Excess of indican in the urine.

The first thing suggested by the above symptoms was peritonitis, for the existence of which as the sole condition spoke the following facts: (1) The initial trauma. (2) Continuous pain and vomiting. (3) Persistent constipation. (4) Freely movable

fluid in the peritoneal cavity. (5) Diffuse meteorism, and (6) The excess of indican in the urine. The absence of tenderness and of fever, as is well known, do not in the least exclude the existence of peritonitis. If we were to consider the above combination of symptoms without reference to the history we could not but diagnose the case as traumatic nonseptic peritonitis.

But was this the sole cause of the above condition of affairs? No, for it would have been difficult to accept the existence of peritonitis as the sole pathological condition. What kind of a peritonitis could it have been that, having begun with such violent symptoms, continued for ten days, then disappeared for eighteen, only to reappear again with somewhat less intense manifestations? Accordingly, peritonitis could not be accepted as the one and only cause of the above complex of symptoms. Intestinal dyspepsia could not be thought of, because vomiting is very rare in that condition, and the history of the case showed no symptoms whatever, that should have preceded such a condition. Moreover, the onset after injury did not speak for this diagnosis. The paroxysmal attacks of pain with and without vomiting, in the three days before our examination, even in the absence of constipation, of necessity directed the attention to the possibility of obstruction or partial occlusion, caused by conditions in or outside of the gut. But it is well known that symptoms of occlusion can appear without the existence of the condition itself, for example, in cases of spastic ileus of hysteria or the paralytic ileus with or without peritonitis. Hysteria could not be thought of in this case. For the existence of paralytic ileus spoke the history of injury, the well marked diffuse meteorism, the pain, and vomiting. But could such a paralytic ileus disappear entirely in order to reappear again after eighteen days? Moreover, the well distributed gurgling sounds could not allow the acceptance of such a diagnosis: in paralysis of the gut, as is well known, there reigns a dead stillness in the abdominal cavity.

The critical consideration of these possibilities compelled us to accept the existence of true mechanical obstruction as responsible for the symptoms. Now, did we have to deal with a stenosis caused by scars in the interior of the gut? This could be excluded, for the history of the case mentioned no illness whatever that could have led to such a condition —no dysentery—no syphilis—no tuberculosis—no typhoid fever. The existence of a new growth could also not be considered: there was no sensation of resistance—tumors are not usually caused by injury—and the time, moreover, was too short to allow the development of a tumor, while the patient's condition showed no cachexia, but only a well marked anemia.

There remained only, among the rarer affections of the intestinal canal, thrombosis or emboli of the mesenteric vessels which may lead to a similar combination of symptoms. This, however, was easily excluded by the absence of any heart or vascular disease. The partial occlusion, then, could be caused by volvulus, by strangulating bands and adhesions, or by intussusception. Volvulus could be excluded on many grounds; it occurs more usually in the sigmoid flexure, there is usually a history of long continued constipation, it is a disease of advanced age, the characteristic stool of stenosis is seldom missed, as well as the localized meteorism (Wahl). Now, it remained for us to decide whether the symptoms of the case, with the light thrown upon them by the history, were caused by intussusception or by strangulating bands and adhesions. We could not, however, accept the existence of the latter condition as yet, because in the first place we failed completely to elicit any sensation of resistance in palpating the abdomen, and secondly, because a very important symptom, that of visible peristalsis, had been absent throughout. Had we at that time made a diagnosis of strangulating bands and adhesions, which we were enabled to do later by the appearance of further symptoms, then it would have been a simple guess on our part. Therefore, we were compelled to make the provisional diagnosis of intussusception.

But even here there lacked an important objective sign, that of the existence of the sausage-shaped tumor of invagination. Yet we had a plausible excuse for the lack of that sign—the tumor may have remained undetected because of the pronounced distention of the intestines. The free fluid in the abdominal cavity, even had we completely given up the diagnosis of peritonitis, did not at all exclude the existence of intussusception. It is self-evident that a bit of the mesentery could have been inclosed in the process, producing stasis in the mesenteric circulation and thus leading to the transudation of free fluid into the peritoneal cavity. The general meteorism spoke somewhat against intussusception; that, however, only caused us to suspect the existence of a second spot affected in the same fashion.

The history of injury and the age of the patient confirmed the above diagnosis. We transferred the supposed seat of the invagination to the small intestine because of the excess of indican in the urine. Such excess alone does not at all indicate that the seat of the affection is in the small intestine, because a pronounced and long continued fecal stasis in the large gut could likewise be responsible for it. In our case, however, the excess of indican spoke for putrefaction in the small intestine only, because constipation and accordingly fecal stasis did not exist for twenty-one days. In explanation of the intussusception we could fall back either upon the spasmodic theory of Nothnagel or the paralytic theory of Leichtenstern.

According to the first theory we could completely ignore the initial local peritonitis. The injury may have caused a ring-like tetanic contraction in one part of the intestines; this acted as the invaginating element over which the part of the gut below the place of contraction was thrown. If you follow the paralytic theory, then we are compelled to assume the existence of primary local peritonitis. A certain portion of the intestine may have been paralyzed and this invaginated into the active nondamaged gut immediately below by becoming everted into the latter's lumen.

The final diagnosis, then, was: Invaginatio partialis enterica, and the father was advised to have the child operated upon.

On the next day we had an opportunity to demonstrate the patient to a number of physicians. The following diagnoses were made: Traumatic peritonitis, Tuberculous peritonitis, Colica flatulenta, Paralytic ileus with and without peritonitis. Dr. Sturmdorf, who was asked especially for surgical advice, was of the opinion that, while a stenosis of the intestinal canal could not be excluded, still the absence of many symptoms prevented him from making that diagnosis, and the seriousness of the operation made him hesitate to recommend an exploratory incision at that time.

Ex concilio, it was decided to place the child in the Metropolitan Hospital, put him on a semisolid diet, wash his stomach, and give high rectal irrigations. The child remained in the hospital for eight

days till November 5, during which time it was carefully observed. No pains or vomiting occurred during this time and the stools were one or two per day of a normal character. The meteorism disappeared almost entirely. The child played, took nourishment with relish, and showed no disturbance of the gastrointestinal tract.

Now the objections against our diagnosis were put before us with renewed emphasis. We were told that the child was not in any serious condition, and that most likely he was suffering from intestinal dyspepsia. This condition would of course become worse at the home of the patient, because a strict diet would not be adhered to. Notwithstanding the striking results of the hospital treatment we continued to insist upon the absolute indication of a laparotomy. In this we were not prompted by a mere curiosity to see the patient's "insides," but because there was one element, the excessive amount of indican in the urine. We reasoned as follows: The child's intestinal tract was thoroughly cleaned out, per os and per rectum; where then existed this putrefaction as shown by the persistence of the excessive amount of indican? The nondisappearance of indican could be explained only by a temporary occlusion in the gastrointestinal canal. However, at the request of the father, the child was discharged from the hospital on November 5.

In the evening of the 9th, we again demonstrated the patient to a number of physicians. Fortunately, an attack of pain occurred during the discussion. Two parallel peristaltic waves were observed between the epigastric region and the umbilicus. Now the existence of an obstruction was evident to all present; yet the consensus of opinion was that the case did not at all call for surgical interference. Naturally the high mortality of operations with the necessary search for the place of occlusion was mentioned, since the place of affection designated by us was not considered proved. Upon our insistence, however, the child was placed in the surgical division of the Metropolitan Hospital under the care of Dr. Sturmdorf. We now took pains to make our diagnosis more exact. The provisional diagnosis of intussusception was of course excluded by the occurrence of visible peristalsis. The diffuse meteorism had already given us cause to suspect, as we have mentioned before, that perhaps another part of the gut was involved by the occlusion. The two waves of peristalsis now strengthened our previous suspicion. The very moment we had given up peritonitis as the sole cause of the above symptoms and accepted occlusion of the gut as the probable diagnosis, the diffuse meteorism could be ascribed almost exclusively to the latter condition. Yet a single occluded part could not produce such a high degree of meteorism and its excess could be due only to a second site of obstruction.

The next few days the child's stomach was washed each morning before breakfast and after the last evening meal. In no instance could bile or pancreatic ferments be discovered in the washings. This absolutely excluded a stenosis of the gut below the entrance of the common bile duct. High seated duodenal stenosis was not to be considered, since we had no symptoms, referable to the stomach. There was no stagnation in the stomach, moreover, and consequently no pyloric obstruction. As is well known, the symptoms of the latter coincide with those of the high seated duodenal obstruction, so that this also could surely be excluded.

The thorough daily palpation revealed to us one day a cord-like resistance in the peritoneal cavity; this extended from the region of the ileum to the left toward the descending colon. In this fashion we could locate more exactly the second suspected place of occlusion; the "X" being discovered we could now easily determine the second unknown quantity. The indican content could have been caused only by an occlusion at a higher level and this, in accordance with the above considerations, could only be the jejunum. Autopsies and laparatomies have shown before that strangulating bands about the jejunum are very common, and accordingly our complete diagnosis was: Subacute partial ileus caused by a strangulating band around the jejunum and adhesions between ileum and the descending colon. Palliative treatment we considered useless, and we therefore surrendered the case to Dr. Sturmdorf for a laparatomy.

Now, what was our explanation of the course of affairs in this case? Because of trauma, there gradually developed a local circumscribed peritonitis, which having run its course without temperature, was not of a bacterial nature. This peritonitis existed as the only pathological condition for either ten days (vomiting, pain, constipation), or for eighteen days, if we do not ascribe the vomiting on the night following injury to shock. Pathologically the peritonitis was of the plastic exudative type. The free fluid in the abdominal cavity was due only to the peritonitis, while the adhesions resulted because of the plastic character of the inflammation. The period of eighteen days, during which the child felt perfectly well, was necessary to afford the time for the formation of adhesions and of the strangulating band around the jejunum. As soon as the adhesions and this band reached a sufficient degree of development there intervened of necessity the first symptoms of obstruction, such as the paroxysmal attacks of pain for the three days preceding our first examination. The adhesions could not be palpated at that time, nor for some time following, because they were forming while the patient was under observation. This case shows therefore how quickly adhesions follow a peritonitis of short duration.

We have presented this case so extensively because it differs markedly from the ordinary run of cases; there were present really only fragments of symptoms, out of which there was to be constructed the whole diagnostic edifice.

In conclusion, I avail myself of this occasion to thank Dr. Sturmdorf for the skillfully performed laparatomy, the more so, as we were under special responsibilities to the child's parents, who allowed the operation only because of our insistence upon the same. Dr. Sturmdorf will communicate the surgical aspect of the case.

123 East Ninety-fifth Street.

BUTTERMILK AS AN INFANT FOOD.

By AUGUST STRAUCH, M.D.,

CHICAGO, ILL.

Dr. Ballot of Holland in 1865 called the attention of the medical profession to buttermilk as an infant food, which had long been used for that purpose among the peasants of Holland and Thessaly. But it was not until the recommendation of de Jager in 1895 and the classic publication of Teixeira de Mattos in 1902 on this method of infant feeding that the use of buttermilk became popular among the physicians of Germany and Holland. Within a short time this method of feeding healthy infants, and especially those afflicted with gastrointestinal disturbances, has found its way into numerous clinics and polyclinics

of Germany. Authorities like Baginsky, Heubner, Caro, Soltmann, Escherich, Salge, and others, have recorded very favorable results. Also in France, Roumania, Greece, and South America buttermilk has recently been tried as infant food with equally encouraging results.

As the term buttermilk is employed to designate various dairy products, it is necessary to confine this term exclusively to churned milk, which may be made by the following methods: (1) Sweet cream, the product of centrifugation, or of milk that has simply stood for hours in a cool place, is churned, whereby the milk-fat globules, after the disruption of their haptogen membrane, form the butter. This buttermilk is almost identical with sweet, skimmed milk. (2) Since a slight acidity of the milk renders the churning more profitable, milk or cream are used which have soured by spontaneous fermentation, or after inoculation with sour milk, or with pure cultures of *Bacillus acidi lactici*. The degree of acidity nearly corresponds to the neutralizing capacity of 5 to 7 c.c. of normal NaOH solution per 100 grams of milk. This buttermilk differs from the aforementioned one by its acidity (due mostly to lactic acid), and by the fact that the casein is coagulated and suspended in the serum in very minute particles.

While the physical, chemical, and biological differences between cow's and human milk correspond to those between a calf's and an infant's stomach, sour buttermilk deviates still more from human milk. The former shows an acid reaction, the latter an amphoteric or slightly alkaline reaction to litmus paper. Human milk is abundant in fat, scanty in albumin, its casein is dissolved and combined with calcium, and coagulable by rennet. Buttermilk is scanty in fat, abundant in albumin, the casein is separated from the lime, and therefore coagulated, and incapable of farther coagulation by rennet. In human milk the calcium salts are mostly suspended as insoluble phosphates; in sour buttermilk we find the calcium partly united with lactic acid; the insoluble di- and tri-calcium-phosphates are converted into *soluble* mono-calcium-phosphates. Human milk is almost sterile, buttermilk in its unboiled state abounds in bacteria, in saccharomyces species, and the products of their metabolism.

These great differences justified the scepticism and reserve in regard to the use of buttermilk in infant feeding until experiments and very favorable experiences removed every doubt as to its great usefulness in certain conditions. Buttermilk, in fact, has been proven to be one of the best dietetic remedies for gastrointestinal diseases of children, according to the medical literature of Germany. Sour buttermilk, however, is not to be administered in its raw primary state, but modified more or less in accordance to Teixeira's formula in the following manner: one liter (quart) of fresh buttermilk is mixed with one or two tablespoonfuls of rice—or wheat—flour, the milk being added gradually at the beginning, to prevent the formation of lumps. While being constantly stirred, it is heated slowly for fifteen to twenty minutes to the boiling point, and finally, after adding 50-70 grams of sugar, it is cooled and hermetically bottled. The addition of sugar makes up for the lack of fat and the resulting deficiency in calories, and so does the flour, which, besides, prevents the formation of coarse, tough coagula during boiling. The formation of these coagula does not occur, however, if the buttermilk is boiled very slowly, so that the boiling point is not reached before thirty minutes. The caloric value of the buttermilk has by this process been increased from about 260 to 600 or 700 units pro liter, thus approaching that of human milk. It contains a high number of caloridynamic units in a small quantity of fluid. The prepared buttermilk is a yellowish fluid, which, after standing, separates into two layers, the upper one consisting of the milk serum, the lower one containing the casein coagulated and suspended in very fine particles. By this fine division it resembles the fine coagula of human milk in the infant's stomach.

The excellent results obtained with buttermilk feeding in Germany induced us to try this method at the Caroline Children's Hospital in Vienna (Director, Dr. Knoepfelmacher), with a result which I consider worthy of reporting on account of its very encouraging features (1903).

In preparing buttermilk, we followed Teixeira's prescription, and administered it in separate bottles of from 50 to 100 grams. The daily quantity amounted in its calorimetric value to 80, 100, 120 units, *i.e.* 120 to 200 grams of milk pro kilogram of the infant's body weight. In acute cases of intestinal disturbance after a period of from one to two days under rice-water feeding, buttermilk was administered gradually in increasing quantities. After improvement had set in, the quantity was increased, not only according to the actual weight, but also to the *age* of the child.

Our own experience includes more than twenty cases, mostly of malnutrition, resulting from chronic gastrointestinal disturbances, with occasional acute exacerbations up to the intensity of cholera infantum; then some cases of *alaitement mixte*, one case of habitual vomiting (pylorospasmus), one prematurely-born child, and one case of icterus catarrhalis. Some of these cases had not responded to other methods of feeding and treatment.

I may be permitted to report in this place a few examples for all, reporting especially the increase of weight of the infants as the most significant indicator of improvement.

1.—Emil Z., two months old, weight 2,000 grams; chronic enteric catarrh, spasms. Weekly increase: 250, 450, and 400 grams.

2.—Rose Z., age two months, weight 3,250 grams; chronic gastroenteric catarrh. Increase of weight in two weeks: 550 grams.

3.—Bruno Sch., age four and a half months, weight 4,600 grams; rachitis, chronic enteric catarrh. Weekly increase in weight: 300, 300 grams, afterwards skimmed milk, which is less well borne.

4.—Walter F., age three months, 4,400 grams; chronic gastroenteric catarrh with acute exacerbation. Weekly increase: 190 and 140 grams.

5.—Julius M., six weeks old; chronic gastroentero catarrh, acute exacerbation. Weekly increase of weight: 260, 300, 400, 400 grams. During the subsequent three weeks bronchitis, with only 200 grams, later on in five days with 300 grams increase. Change to skimmed milk is followed by diarrhea.

6.—Rudolf St., sixteen days old, weight 2,300 grams; prematurely born child; too weak for nursing. Increase of weight in seven days: 240 grams. The following week exclusively breast feeding, with a loss of 90 grams in weight.

7.—Anne K., five weeks old, 3,000 grams, breast child; weak movements in suckling; dystrophy; mother's milk abundant. During feeding with buttermilk, besides breast, weekly increase: 400, 300, 250, 100, 200 grams. Within the ten next days, 200 grams; the following week, 300 grams. Exclusive breast feeding, with weekly increase of weight of 50 to 100 grams.

8.—Anna Dr., two months old, weight 1,900

grams; chronic intestinal catarrh with acute exacerbations, atrophy. Rice-water diet; calomel; then buttermilk. Increase of weight in six days, 150 grams, the following ten days 250, the next week 200 grams.

9.—Karl H., five months old, 3,900, breast child; dyspepsia, eczema universale. The latter disappeared after a short time of buttermilk feeding. In the beginning buttermilk was not well borne. First loss, but soon increase of weight 200 and 350 grams weekly.

10.—Anna F., three months and twenty days old, weight 4,400 grams; habitual vomiting (pylorospasm); breast child; excessive vomiting after each breast feeding, also when fed with diluted cow's milk and with rice water, given in teaspoonful doses; irrigation of stomach without result; buttermilk (at first in teaspoonful doses) checks the vomiting at once. In the first week 100 grams increase of weight.

11.—Hans Z., three months old, weight 2,650 grams; catarrhal icterus, with tendency to constipation; milk-sugar, artificial Carlsbad salt, and buttermilk feeding. The icterus disappeared soon. Weekly increase of weight: 200, 250, and 150 grams.

12.—Josephine K., three months old, weight 3,500 grams; chronic dyspepsia, eczema; buttermilk feeding. Increase of weight the first week: 250 grams; the next four days 120 grams. The child became ill with pneumonia, and, in spite of this, gained 70 grams during the following five days and 130 grams the following week. Without buttermilk the baby gained within the next two weeks only 50 grams, but after reestablishment of buttermilk feeding, 250 grams the first week, and 1,700 grams during the two following months. The eczema disappeared very soon.

13.—This case shows the danger of a sudden change from buttermilk to another food. Karl U., ten months old, 6,600 grams; chronic entero catarrh. Various methods of treatment had been tried without result. While the child was fed with buttermilk the weight increased in four days 200 grams; the following twelve days 300 grams. Then the mother, without our consent, fed the baby with cow's milk and noodle soup. Soon incontrollable vomiting and diarrhea set in, followed by convulsions and exitus letalis.

A failure was the following case:

14.—Anna T., 4,300 grams weight; cholera infantum, resulting in chronic enteritis. We tried besides buttermilk feeding other methods, but all in vain, and the child died after four weeks of treatment under the symptoms of hydrocephaloid.

The increase of weight during buttermilk feeding is accompanied by a general improvement. The babies become quiet and good-natured, they sleep well, and have a good appetite. Vomiting ceases, or becomes less frequent; the frequency of the stools lessens, although they may occur oftener than in normal breast-fed babies. The stools are usually yellow, homogeneous, pasty, and of a neutral or alkaline reaction. But even in cases where the quality of the stools did not satisfy our expectation, and where we had to dilute the prepared buttermilk with small quantities of rice water, we observed a good increase of body weight. All the babies liked the buttermilk, even as an addition to breast feeding.

Our encouraging experiences being limited to a comparatively small number of cases, I will briefly review the results of others, based on a larger experience, to show how excellent a remedy and food buttermilk has been proved to be. The excellent experiences of Teixeira are so numerous that they have been the principal inducements for similar experiments in Germany. His six years' experience covered many hundreds of cases which not infrequently manifested a weekly increase in weight of from 500, 600, to 700 grams. Baginski's observations range over 182 cases in the medical wards of the Emperor and Empress Frederick Hospital of Berlin. In 150 the results were excellent, in the remainder the improvement was less pronounced; in 32 children the feeding was unsuccessful. In the entire hospital he had fed 300 children with buttermilk with similar results. A few children were taken directly from the breast and given buttermilk because the mothers could not visit the hospital to nourish their children.

Salge reports 85 cases with very satisfactory results out of 119 babies, who were fed with buttermilk for dyspepsia, chronic entero catarrh, atrophia, and in *allaitement mixte*. In the remaining cases buttermilk failed, but so did also other methods, including human milk.

Jean Cardametic (Greece), Rensburg, Leschziner, Escherich (Vienna) had similar experiences, and Dr. Riether, primarius of the foundling institution of Vienna, stated that atrophic babies thrived excellently on buttermilk after other foods had been tried in vain. He found the remarkable fact that breast-fed babies, who had been dystrophic without determinable cause, showed a remarkable increase in weight and improvement if small quantities (one teaspoonful to one tablespoonful) of buttermilk were administered before each breast feeding. He supposes this to be due to the digestion-promoting action of lactic acid, which perhaps may also account for the good results obtained from buttermilk feeding in *allaitement mixte* of healthy babies.

Teixeira's original method of preparing buttermilk has often been modified to meet special indications. For instance, the flour has been partly or entirely replaced by various dextrinized flours (Kindermehle) for babies in the first weeks of life, or for babies whose feces showed upon microscopical examination, or with the iodine test, starch in a greater amount, indicating insufficiency of starch digestion.

In extreme intolerance of carbohydrates the flour can be dispensed with entirely, and even the sugar may be replaced for a short time by some other sweetening substance (saccharine). The low percentage of fat in buttermilk has been increased with the best results (Rommel, Rensburg, Schlossmann, Heubner) by the admixture of cream or sesame oil, when buttermilk alone did not give satisfactory results, and an increased amount of fat was needed. For it is evident that fat cannot be replaced by carbohydrates, even isodynamically, for an indefinite period of time, since the principle of isodynamic substitution is not applicable arbitrarily or without limit; indeed, in some cases the poverty of fat in buttermilk may be a drawback.

Considering the almost paradox composition of an infant food of such approved, undoubted value in various intestinal disturbances which so often accompany artificial feeding, attempts at explaining these facts become very interesting. The unexpectedly good results obtained from this food which is so rich in albumin have been explained by the relative lack of fat; but experiments with simple skimmed milk (Knoepfelmacher) and the fact that the addition of cream aids the good results obtained in many cases do not support this supposition. The easy digestibility of the casein of buttermilk is almost universally admitted; it is probably due to the distribution of the former in extremely fine floccules as a result of the mechanical process of churning. In addition, the acid reaction, the abundance of carbohydrates, with their acid products of fermen-

tation within the intestinal tract, may perhaps protect the albumin from more intense putrefaction and influence the reaction of the soil of the intestinal bacterial flora.

According to Rubinstein's investigation, pathogenic bacteria (of diphtheria, typhoid, tuberculosis, *Bacillus pyocyaneus*), as a rule, gradually perish spontaneously in buttermilk, both on account of the increasing acidity and the presence of the *Bacillus acidi lactici,* or they are easily destroyed by boiling for only one, two, to three minutes. We further know that the acidity of the food promotes tryptic digestion, as the acidity of the stomach contents energetically stimulates (Pawlow) the secretion of trypsin. The digestibility of the nitrogenous substances of buttermilk lessens the work (Heubner) of the glands of the stomach and the intestines; the amount of energy thus spared is beneficial to the organism of the baby.

As to the indications for the use of buttermilk, no absolute rules can be formed, nor is any strict classification of the various intestinal disorders unanimously accepted. Buttermilk has been used with best results in insufficiency of fat—and of albumin—digestion; in atrophia infantum, dependent on chronic entero catarrh; in dystrophia infantum without determinable causes; in *allaitement mixte,* and in cases of sudden weaning. The high calorimetric value of the buttermilk renders it fit for feeding prematurely-born babies who are not able to nurse, or if no wet nurse can be promptly secured. Many babies with intestinal diseases digest only buttermilk; others digest other foods as well. As a rule, acute intestinal disorders, and those chronic disturbances due to prolonged starch feeding, should be excluded. In case of intolerance for carbohydrates, buttermilk without flour, or even without sugar, may be tried for a short time.

The objections against a buttermilk régime are due to the fact that buttermilk of standard quality, which is indispensable for success, can be obtained only with great difficulty in large cities. The common commercial so-called buttermilk is indeed too often unfit for infant feeding on account of its contaminations, its unhygienic manipulation, and its ureliability with reference to acidity.

To meet these objections, pure conserves of buttermilk are prepared in Germany, and have been tried with success in clinics under the supervision of leading pediatrists. They are worthy of a trial wherever genuine buttermilk cannot be secured.

Hydrastis.—J. M. French says that he believes that hydrastis is a valuable drug. As a stomachic and general tonic, the crude drug and its galenic preparations may be employed. To produce contraction of muscular and connective tissue, berberine is the preferred agent. To cause contraction of the arterioles, hydrastine and hydrastinine are effective, and of these hydrastinine is especially superior as a uterine hemostatic.—*American Journal of Clinical Medicine.*

THE RELATIONSHIP OF CLINICAL SYMPTOMS TO MICROSCOPICAL FINDINGS IN CASES OF CARCINOMA OF THE UTERUS.

By C. O. THIENHAUS, M.D.,
MILWAUKEE, WIS.

Of all scourges which since the early existence of humanity have devastated and terrorized mankind, none up to the present time has been able to resist the penetrating searchlight of microscopy, bacteriology, and chemistry so obstinately and, unfortunately, so successfully, as carcinoma. In the same manner as during the time of Hippocrates and Aulus Cornelius Celsus, the physician and surgeon of to-day is forced to battle with cancer as an enemy of whose origin, mode of living, and strength he knows but little, if anything, and with full justification his position then, as now, can be compared to that of a general who is compelled to accept battle without sufficient reconnoitering against an enemy, whose quality and quantity is unknown to him, and who is sheltered by the darkness of night and entrenched in a seemingly impenetrable position.

However, time and scientific progress have been grinding slowly but surely, and have destroyed gradually a few outlying forts of the enemy's fortress, and although all efforts of detecting the *"fons et origio"* of cancer have been unavailing and many elegant hypotheses have proven to be nothing but *chateaux en Espagne* and have had to disappear from the horizon of scientific truth like the *fata morgana,* still our clinical results, achieved in this combat, show a decided gain, and surgery of to-day can claim to have reduced the mortality of cancer from almost 100 per cent., as existing during the time of Hippocrates, to a mortality of about 60 per cent. In other words, at the present time surgery is enabled to save, according to circumstances which will be illustrated later, from 25 to 50 per cent., conservatively speaking, of all carcinoma patients.

The reasons for this wonderful success and changed state of affairs are, as known to all of us, twofold: First, the phenomenal advancement of surgical technique, based upon the epoch-making discovery of Lister; an advancement of technique which, in regard to carcinoma operations at the present time, has been pushed to the utmost degree of perfection and seems almost to have reached the limit of human possibility; second, the advancement of clinical diagnosis and microscopic pathology. Thus we are enabled first to demonstrate conclusively that carcinoma in the incipient stages of its development is a local disease, and, based upon this fundamental dogma, second, to make our diagnosis in its early stages, at which time our now perfected surgical technique can be employed most effectively, and can reap its just reward: *Sanatio completa.* To achieve this purpose fully, however, and to make the diagnosis of carcinoma in its earliest stages possible, it is absolutely essential that the study of clinical symptoms go hand in hand and be interwoven, so to speak, with the study of microscopical pathology. That they are inseparable from each other, and that in each individual case the pathological examination by the microscope has to speak the last and decisive word in regard to diagnosis of carcinoma; in fact, that without it such a diagnosis has hardly any merit from a scientific standpoint, can best be demonstrated by a study of the relationship of clinical symptoms to microscopical

findings in cases of cancer of the uterus, with which this paper has to deal.

It is hardly possible within the limits of one article to go into minute details, and as this paper is addressed to the general practitioner, and not to the specialist, such details are not necessary. Its scope will be held within the boundaries of a general survey, emphasizing chiefly those points which are essential for the purpose of recapitulating, and, if possible, of advancing the knowledge of the general practitioner to the early diagnosis of carcinoma uteri.

What are the clinical symptoms pointing to a possibility of a malignancy of the uterus in the individual case—symptoms which must make it necessary for the general practitioner to make immediately a thorough clinical examination of the female genital organs of the patient?

A. When a woman over fifty years of age has entered the climacterium, and after some months of cessation of the menstrual flow, notices a bloody discharge or even a watery sanguineous discharge from the vagina, there exists strong suspicion of carcinoma of the uterus, and an immediate physical examination of the generative organs is imperative. The vulva and vagina should be examined thoroughly and the cervix uteri inspected. If it is found that no growth or ulcerative or catarrhal process is present in these organs to explain the symptoms, and that bimanual examination does not reveal the presence of a tumor of the uterus or adjacent organs as a remotely possible source of the bloody discharge, then it is necessary that a thorough currettement of the body and of the cervix uteri be made. All scrapings obtained by this curettement, performed in a most thorough manner, so as not to overlook a beginning carcinomatous growth in the tubal cornua of the uterus, should be saved and preserved in a 4-10 per cent. formaldehyde solution for microscopical examination, either by the practitioner himself, if he is competent for this specialistic work, or by a competent gynecologist or pathologist. If during the curettage we find that the inside of the uterus is uneven or rugged, or if large masses of tissue easily gave way during curetting, our suspicion of carcinoma of the body of the uterus receives further confirmation and is clinically almost a certainty, but the accurate scientific diagnosis only the microscope is able to reveal, as the same clinical symptoms may be found in cases of submucous and interstitial fibroid of the uterus which has undergone necrotic or sarcomatous degeneration, or in cases of sarcoma of the corpus uteri; mucous and fibroid polypi originating from the cervical canal or the cavity of the uterus; glandular endometritis, and very rarely tuberculosis of the corpus uteri. However, we all know in cases of myoma of the uterus the climacteric very seldom begins before the fiftieth year, but usually much later, and that in cases of submucous fibroid the patient usually gives a history of menorrhagia and metrorrhagia occurring before the age of fifty. That such menorrhagia and metrorrhagia between the age of thirty and fifty is furthermore oftentimes the first clinical symptom of cancer of the portio and the cervix uteri, will be considered later.

Cancer of the body of the uterus usually occurs between the ages of fifty and sixty, and in the predilection for this age it resembles sarcoma of the corpus uteri. It is furthermore well known and proven by statistics that of all cases of cancer of the uterus, carcinoma of the corpus gives the best surgical results, because its virulency (so-called) or its tendency to produce metastasis, and to spread to the broad ligament and adjacent organs, is less pronounced than in cases of cancer of the cervix. As an illustration, I will here only briefly mention the operative results in cases of cancer of the uterus from Chrobak's clinic, Vienna. According to his statistics, published recently by Blau (*Beiträge zur Geburtschülfe und Gynäcologie,* Bd. 10, Heft. 3), he performed from January, 1890, to October, 1903, 309 vaginal hysterectomies for cancer of the uterus. Of these, 87.7 per cent. were cases of cancer of the cervix uteri, and 11.5 per cent. cases of cancer of the corpus uteri. Seventy-five per cent. of the cases of cancer of the corpus were permanently cured, that is, there was no recurrence after three years; from the cases of cancer of the cervix only 40 per cent. were cured. Because of this great possibility of permanent cures of cancer of the corpus uteri, it is extremely deplorable when such cases come too late to the surgeon, in a state, for instance, when the carcinomatous growth has penetrated the entire thickness of the wall of the uterus, and has produced metastasis within the peritoneal cavity. About three years ago I had the misfortune of observing such a case, which gave the following history: Mrs. K., from M., Mich., fifty-four years of age, states that she ceased to menstruate at the age of fifty. Two years later a bloody discharge made its appearance, which she believed was nothing extraordinary, but merely a renewal of her old menstruation. The discharge became more copious later on, and was at times of a foul smelling character. This,

FIG. 1.—Adenocarcinoma of the corpus uteri.

together with some pain in the lower portion of her abdomen, was the incentive (two years after the appearance of the first symptoms) to consult a physician, Dr. Y., who called me in consultation. Bimanual examination revealed no abnormalities in the vagina or cervix. The body of the uterus was enlarged to double its normal size, and was painful to pressure; a bloody, foul discharge exuded from the external os. The microscopical examination of some scrapings kindly made by Dr. Beffel, the microscopical drawing of which (made by Dr. Ruhland) is herewith reproduced on Plate No. 1, showed that we had to deal with an adenocarcinoma of the corpus uteri. During the operation, performed by the combined vaginoabdominal method, it was found that metastatic growths had already formed within the peritoneal cavity. One of these, as large as a walnut, was removed, and plate No. 2 reproduces a microscopical picture of this metastatic growth. The woman recovered from the operation, gained in strength for one-half year, and died one and one-half years later, a victim of her own ignorance and superstition. According to the excellent results, which, as already pointed out, surgery can achieve in cases of cancer of the body of the uterus, this woman's life could almost certainly have been saved if immediately following or within half a year following the beginning of her clinical symptoms hysterectomy had been performed.

In case that during an examination a polypus is encountered as the underlying cause of the metrorrhagia, this polypus must be removed thoroughly at the base of its insertion to the cervical or uterine wall, the uterus curetted, and polypus and scrapings subjected to a microscopical examination. Although most polypi are of a mucous or fibrous nature, they sometimes undergo carcinomatous degeneration. It is furthermore advisable to keep all patients from whom uterine polypi have been removed, under strict observation for the next one or two years, because of the possibility of the recurrence of the

FIG. 2.—Metastatic growth in the peritoneal cavity. A case of adenocarcinoma of the corpus uteri.

polypi and the future development of malignancy. The following observation of my own will illustrate this point. Mrs. E. M., from M., Wis., forty-eight years old, complained that for six months she had been suffering from menorrhagia and metrorrhagia. The examination revealed a polypus protruding out of the external os. The uterus was curetted and the polypus removed. The microscopical examination, as shown in plate No. 3, showed that there was no malignancy present. One and one-half years later the menorrhagia returned and another polypus of benign character had to be removed. No further disturbances since this time.

In case a tumor of the adnexa is encountered as underlying cause of the menorrhagia, a laparotomy has to be performed, and if the tumor proves to be a malignant growth, it is necessary to remove the uterus and the adnexa on the other side of it, because a metastatic growth may have already developed or may develop later on in the body of the uterus or the ovary. I observed one case in which a benign tumor

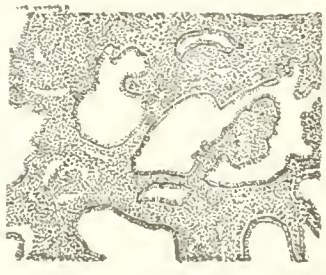

FIG. 3.—Polypus cervicis uteri

of the left ovary, a fibroma the size of a man's fist, was the underlying cause of excessive post-climacteric menorrhagia and metrorrhagia. These subsided promptly after the removal of the fibroma ovarii.

B.—When a woman from thirty to fifty years of age complains of frequent menorrhagia and metrorrhagia, and furthermore points out that bloody discharges, intermingled with leucorrhea, occur during or following coitus or vaginal douching, there again exists strong suspicion of carcinoma—the probability being that the portio vaginalis uteri is the seat of the disease. If, during examination of the patient, we detect a growth or ulcerative process on the portio vaginalis, easily bleeding or even crumbling from manipulation, then the diagnosis of carcinoma is, from a clinical standpoint, almost a certainty. In such cases a piece of portio containing both healthy and diseased tissue should be excised under antiseptic precautions and examined microscopically. It is well known that the findings and symptoms above referred to—such as bleeding during coitus, friability, etc.—which point so strongly toward the diagnosis of cancroid or cauliflower carcinoma of the cervix, may also be found in cases of simple erosion of the portio vaginalis.

The two patients from whom were taken the tis-

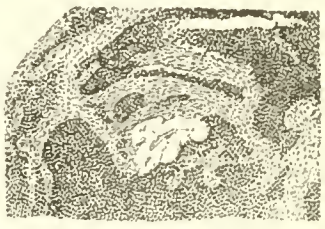

FIG. 4.—Cancroid of the cervix uteri, showing areas of hyaline degeneration.

sues illustrated in plates Nos. 4 and 5, demonstrate this point very clearly. In both these cases the diagnosis of carcinoma of the cervix uteri had been made by several physicians on the basis of the clinical symptoms and physical findings. In the first case (plate No. 4), the microscope confirmed the diagnosis, and showed that we had to deal with a cancroid of the portio vaginalis, hyaline degeneration being present in some places. In the second case, as shown in plate No. 5, the microscope showed that the process was a purely inflammatory one. Curettage and partial excision of the cervix was advised and performed in this case three years ago, and the patient has enjoyed perfect health ever since.

At this point I would like to sound a warning against the indiscriminate cauterization of what appears to be simple erosions of the cervix, without first confirming the diagnosis with the microscope. Many cases are cited in the literature (and naturally many more are never reported at all for obvious reasons) in which during the delay from cauteriz-

FIG. 5.—Erosion of the cervix uteri showing round-celled infiltration.

ing, what was supposed to be a simple erosion of the cervix, an unsuspected carcinoma is allowed to pass the stage of surgical operability. On the other hand, it is hardly necessary to point out once more that statistics of surgeons who claim to have cured so many cases of cancer of the cervix uteri are absolutely worthless without the confirmation by microscopic examination in every case.

The greatest obstacles to early clinical diagnosis are encountered in those cases of carcinoma of the cervix uteri which originate from the epithelium of the mucous membrane above the external os, or from the epithelium of the deeper glands of the same region. In such cases the clinical symptoms of menorrhagia and metrorrhagia occur so late

that the patient seldom consults her physician for relief until all hope of radical cure has vanished. In the examination of such cases the physician is apt to find that, while the external os may be of its natural size and appearance, immediately above it a crater-like cavity, lined with friable tissue, is encountered. In addition to this, hard nodules or infiltrations may be found on one or both sides of the uterus—the result of extension of the carcinoma into the broad ligament.

C.—If, during an abortion, an hydatid mole is encountered, and if after a lapse of some weeks hemorrhages occur in spite of the previous thorough emptying of the uterus, either by curettement or digital ablation, there is again suspicion that one of the most malignant forms of carcinoma may have developed on the basis of the mole, namely, chorion-epithelioma or deciduoma malignum. This form of carcinoma may, though rarely, follow a simple abortion. If, therefore, hemorrhages persist after thorough and possibly repeated curettement of an abortion case, such a possibility must be borne in mind. If during the examination of a case such as just referred to a soft tumor is found within the vaginal wall, this tumor should be carefully examined microscopically, for cases are on record where, following the expulsion of a hydatid mole, or even after simple abortion, primary chorion-epithelioma has developed in the vaginal wall without the presence of any similar growth in the uterus at all. Some authors even go so far as to advocate hysterectomy in every case of hydatid mole, believing that a hydatid mole *per se* is the beginning of a malignant process. This advise, it seems to me, is a little too radical.

In summing up, if we ask ourselves why is it that in cases of cancer of the uterus women consult the physician usually at a period when radical cure by surgical means is out of the question, we must attribute this to two causes—first, to gross ignorance on the part of the public in regard to cancer in general and especially its early symptoms, and second, to the insidious character of the disease. I have already referred to the prevalent belief that, when after the climacterium has set in, hemorrhages occur, these hemorrhages are nothing more than the reappearance of the natural menstrual flow, or a natural rejuvenation. Another erroneous belief, strongly prevalent among the public, is, that hemorrhages from the uterus without pain cannot be cancerous in origin. We all know that pain in any case of cancer of the uterus, in the absence of any inflammatory process, almost invariably indicates that the neoplasm has extended beyond the limits of the uterus itself, and that our prognosis, as far as a radical cure by operation is concerned, must be *valde dubia aut pessima*. This ignorance on the part of the public must be overcome before we can ever hope for any material improvement in our surgical results. In this matter every physician should consider it his duty to help dispel the dense ignorance of the masses by education. Great progress has already been made in this respect in Germany by such gynecologists as Winter, Duehrssen, and others, who by public lectures, magazine articles, and circular letters of instruction to midwives, are meeting with great success in reducing the mortality from uterine carcinoma by education of the masses.

To combat successfully the insidiousness of carcinoma, it is imperative for the practitioner to make careful and conscientious clinical, and, if necessary, as above illustrated, microscopical examinations in dubious cases, and it is better for him in case of doubt to share the responsibility with the specialist, than to resort to dilatory and experimental therapeutics.

At the same time we sincerely hope and trust that the great efforts now being made in the various cancer laboratories of the world to determine the genesis and nature of the scourge may be crowned with success in the near future, and that the darkness of the pestilence may soon be dispelled by "*mehr Licht.*"

Post Graduate Hospital.

ILLUSTRATIONS FOR MEDICAL JOURNALS.

By A. J. MARTIN,

PATHOLOGICAL ARTIST

NEW YORK

Among the medical journals of the world, those of the United States are far away ahead in the comparatively new departure of illustrations. In this age of hustling and competition the ever-busy medical practitioner who glances at his journal in what spare time he can afford, expects as a matter of course to find fully illustrated articles. The illustrated medical journal has become a necessity; it has come and come to stay.

Fig. 1.—Line drawing from a case of fungating sarcoma, showing the type of illustration best suited to journal work.

Now a word, in brief, as to the adaptability of the different methods adopted in illustrating medical articles. It is a not uncommon fallacy to suppose that an etcher can produce a good block out of anything. Let him be supplied with as good an original as is procurable.

Without doubt, line—pen and ink—drawings stand preeminent. They are in most cases sufficiently comprehensive, and reproduce better and more cheaply than half-tones made from wash drawings and photographs. And nothing is more pleasing than a well-executed line drawing. This fact is indeed particularly true in journal work when one remembers that the paper used is uncalendered and the printing done very rapidly.

Photography is to-day playing a great part in il-

lustrating our journals. Some men prefer it because they say the camera cannot lie. But I aver that, with comparatively few exceptions, photographs that have not been "touched up" and transformed literally into drawings, do not furnish good

Fig. 2.—From an untouched photograph of a case of mediastinal tumor, with swelling of the glands of the neck on the left side and edema of the upper lid of the right eye; numerous dilated veins were present in the skin covering the thoracic swelling.

material for a successful reproduction. Figs. 2 and 3 well illustrate this point.

Wash drawings, possessing strong contrast of light and shade, make beautiful half-tone reproduc-

Fig. 3.—From the same photograph as Fig. 2, after retouching to bring out the salient points

tions, and are in great favor at the present day. But, to my mind, this class of illustration is more suited to works in book form than to the journals, where expense in reproduction is a more serious matter.

As to color work little need be said. There is a wreath of laurels awaiting the man who will devise a method of reproduction in natural colors sufficiently cheap to enable our editors to delight their readers with this form of illustration. But this is an age of rapid progression, and I confidently believe that the time is not far distant when our medical journals will be much more interesting pictorially than they are at the present day.

The Opsonic Index in Relation to Tuberculous Peritonitis.—Arthur H. White calls attention to the surgical cures of certain cases of tuberculous peritonitis by the flushing of the peritoneal cavity. In relation to this well known fact the author speaks of the recent work of Wright, who has shown that there is present in the blood a protective substance hitherto unknown, which he calls opsonin. To the presence of this substance phagocytosis is largely due. This investigator has also shown that in cases of local tuberculosis the blood contains less opsonin than that of normal individuals. The opsonic index may be raised by the inoculation of a tubercle vaccine. He has proved that in raising the opsonic index and keeping it steadily at the normal, or higher than normal by means of inoculation, ultimate complete cure of local tuberculosis will result. The writer believes that operations should still be performed in these cases, because they furnish the only or the best means of getting rid of the fluid poor in opsonin and of promoting the necessary exchange which occurs between the blood and the locally infected area. It will be well also to raise the opsonic index before operation by inoculation. The after-treatment should include blood examinations from time to time to determine the degree of the opsonic index.—*The Dublin Journal of Medical Science.*

Torsion of a Hydrosalpinx.—Some fifty cases of this condition are already on record and renewed interest in the subject has been aroused by the report of a recent case by Dr. Albert Martin, which is editorially reviewed in the *British Medical Journal* of January 19, 1907. The patient, thirty-four years old, not pregnant, supposed herself threatened with a miscarriage. Nine years previously she had suffered from a violent attack of pain in the hypogastrium, chiefly towards the right side, with abdominal distention. She kept her bed for a month, and recovered spontaneously; no diagnosis being made. The illness which led her to consult Dr. Martin was a return of the abdominal distention, with diminution of the catamenial flow. On this occasion the acute attack followed instead of preceding the distention. It came on when the patient was finishing her lunch, and was very severe, chiefly in the right iliac fossa, radiating down the lower extremity. As she had suspected pregnancy, the acute attack was taken by the patient for threatened abortion. On examining the pelvis Martin detected a tender swelling in the right fornix, reaching into Douglas' pouch. It suggested torsion of the pedicle of a small ovarian cyst. Abdominal section was performed, and a large hydrosalpinx of the right tube was discovered. It resembled superficially a coil of distended strangulated intestine, and was twisted two turns on its pedicle. It is significant that there were no adhesions, and as dilated tube is very common but not often twisted, yet usually more or less adherent to adjacent structures, the cause of the relative rarity of torsion is clear. Ovarian cysts often rotate on their pedicles, but they are much heavier than tubes and therefore not so readily fixed by adhesions. An instructive discussion followed the reading of Dr. Martin's monograph. Siredey related a case where a lady was attacked suddenly with "enteritis" when at a watering place. A tumor was detected; it proved to be a large hydrosalpinx with twisted pedicle.

New York, March 30, 1907.

THE EVIL OF EXAMINATIONS IN MEDICAL EDUCATION.

WE are constantly hearing so much about education in all its aspects that the mention of the subject is a suggestion of boredom. We think it must have required some courage to announce an address on the "true aim of medical education and the evil of the examination fetich" as a commemoration of John Hunter. This course was adopted, however, by Dr. Lauriston Shaw, physician to Guy's Hospital, London, who delivered the oration at the Hunterian Society on February 15, and succeeded in imparting to his discourse a degree of novelty which was as unusual as the lesson he inculcated was important. It came as a surprise at the outset that Hunter's defective preliminary education, with his later extraordinary mental development, and even his tragic sudden death, should be cited in support of the theme. Not that it was suggested that his amazing work and development were to be considered due to the fact that he could not have passed the equivalent for his day of one of our preliminary examinations when he began his life work. But it was an open question whether a school and college course might not have produced a merely successful practitioner instead of one of our most brilliant thinkers. Possibly his protest against the requirement of preliminary instruction, in the excitement of which he expired, was occasioned by the recognition that such barriers would have shut him out from the career in which he must have known that he had attained remarkable success. Dr. Shaw referred to Hunter's crabbed style as due to his defective early education, and commented on the rarity of the two-fold power of searching out the hidden facts of nature, and telling in clear language the truths one has found; but a facile pen might have drawn him from the bench to the writing table, and, after all, "if he could have told us more fluently what he saw, would he have seen so much?"

The lecturer proceeded to show the blighting influence of the examination system on both teachers and pupils. He maintained that the fetich of examination is gaining a hold year by year, that its influence is wholly detrimental, and its effects demoralizing. Yet it would be easier for medicine than for some other studies to free itself from this evil. The ideal examination of those who worship the fetich is conducted by one who knows the candidate only as a number. How can he test the powers of the mind? One point he can try, that which is commonly spoken of as "the knack of passing," the ability to keep a store of facts on the surface and pour them out rapidly in presence of a stranger—a power essentially depended on by the crammer—"a mixture indeed of memory and cheek." Dr. Shaw admitted this power was an attribute of mind, just as bulk is of muscle, but said to worry a man who wants to develop his mind with continual investigations of his memory was as senseless as periodically to test the lifting powers of a man who was learning the violin. As in one case, the subtle power of coordination would be lessened, so in the other case would cramming deteriorate the higher intellectual faculties. No sooner does the medical student become acquainted with his teachers than the chilling specter of the examiner comes between, and both are handicapped at every step by the question, "Will this pay at exams?" Dr. Shaw admitted that after his twenty years' teaching, he knew too well what would pay in this way, and he knew, too, that many a student's desire for knowledge, power of observation, capacity for reflection, judgment, and reasoning faculties have been crushed by the domination of the examination fetich. In no calling are the highest faculties more necessary than in ours. It is useless to develop only a power to collect facts in a man destined to practise. A man primed with a knowledge of the possible beliefs of his examiners may be incapable of exercising a sound judgment of such beliefs. No mass of facts in his memory will serve in diagnosis the man who has not trained his eyes, ears, and fingers as well as his brain.

Dr. Shaw would have inspection replace some of the examinations, and records of work done allowed to count toward marks for qualification. He would have bedside work and that done in the post-mortem room and in the laboratories given their proper value. Tangible results of a student's work could be judged by his clinical records, his charts, his bacteriological, chemical, and hematological reports, together with duly attested microscopic slides, heart and pulse tracings, photographs, drawings, and so on, to be kept available for surprise visits of the inspector. Much better would such a record be than examination tips by the crammer. Dr. Shaw believed that such inspection would ultimately be acclaimed as a means of "overthrowing the examination fetich and allowing us to attain the true aim of medical examination." The author of this address from which we have quoted is to be congratulated on his courage in stating his views, and still more perhaps on his own escape from the evils of the fetich of which his university (the London) was so long the high altar.

RELATION OF ENDOTHELIOMA TO CANCER RESEARCH WORK.

A DISCUSSION of this question was recently held before the Glasgow Medico-Chirurgical Society, the paper of the session being presented by Dr. W. S. Lazarus Barlow (*Lancet*, March 9, 1907). After a description of the various forms of endothelial cells, the essayist indicated the distinguishing histological features between the endotheliomata on the one hand and angiosarcomata and certain varieties of spheroidal and squamous-cell carcinomata on the

other. He believed that a considerable number of the growths found in the breast and in the cervix uteri, which were described as spheroidal-cell carcinoma and squamous-cell carcinoma respectively, were in reality examples of lymphatic perithelioma. The cases to which he was referring were those in which masses of cells were present with a central degenerated material. It had been usually considered that this degenerated material had arisen from a necrosis of the central portion of a formerly completely solid mass of cells, but he pointed out that under such conditions there should be a gradation between the outermost and undegenerated cells and the central degenerated mass. On the contrary, in the cases under consideration there was a sharp differentiation between the cellular portion and the débris, and in addition a definite endothelial lining, such as one was accustomed to meet with in the ordinary blood-vessel or lymphatic, often bounded the proliferated cells on their internal aspect and completely shut them off from the central débris. He urged further that these cases were identical in histological appearance whether they were derived from the breast or the cervix and were best explained on the view that they were lymphatic peritheliomata.

The greatest difficulty in differentiation lay between the endotheliomata and those carcinomata containing the so-called Malpighian and the pure prickle cells. In examining the sections from cases in a certain hospital for a period of six years or more, he had found that about 10 per cent. of supposed breast cancers and the same number of uterine cancers should, on the ground of his own researches, be considered as endotheliomata. There was evidence that the endotheliomata were amongst the most malignant of new growths. On the other hand "parotid tumors" and certain tumors of the cerebral meninges showed that growths which were histologically identical with those that had been described might be non-malignant in respect of the fact that they did not tend to recur after removal. It was clear, therefore, that endotheliomata might be intensely malignant or non-malignant, and the important question at the present time, bearing in mind the amount of work that was being done on the subject of mouse cancer, was to determine in what class of growths this latter should be included. A recognition of the true character of mouse tumors was necessary for determining whether work on these growths was attacking the cancer question at its very heart, which would be the case if they were carcinomata, or whether it concerned a relatively uncommon form of new growth—namely, the endotheliomata. Moreover, supposing that the majority of mouse tumors were ultimately considered to be endotheliomata there remained the question as to whether they belonged to the intensely malignant or to the non-malignant variety.

THE MILK SUPPLY OF NEW YORK.

An interesting symposium on the milk supply of large cities was held at the Academy of Medicine two weeks ago, a report of which was published in the Medical Record for March 23. At the present day the proper supervision of the milk supply is recognized by all as being a matter of paramount importance, and all the best authorities are agreed that the public health boards should be allowed considerable power in dealing with the subject; it is interesting, however, to see the difference of opinion among the experts as to the direction this control should take. That it is possible to supply an extremely pure raw milk has been shown by the dairy farms certified by the Milk Commission of the County Medical Society. But the measures necessary to produce such a milk place it beyond the reach of the ordinary individual, for it is absolutely impossible to sell certified milk in New York for less than twelve cents a quart, and there is but little for sale under fifteen cents.

What, then, can be done? The answer to this must be governed largely by our knowledge as to the prevalence of diseases traceable to milk. So far as tuberculosis is concerned, the recent careful researches of Ostertag show that cows reacting to tuberculin, but presenting no clinical evidences of tuberculosis, rarely excrete tubercle bacilli in the milk. On the other hand, with cows showing manifest signs of, for example, tuberculosis of the lung, there is often an enormous excretion of tubercle bacilli in the feces, and these are readily carried into the milk. The clinical evidence as to the frequency of infection through milk must also be considered, and while most pathologists here are agreed that this mode of infection obtains in only a small percentage of cases, it nevertheless does quite certainly occur occasionally. One of the speakers at the meeting to which we have referred described an extensive outbreak of scarlet fever traced to infected milk in Boston, and the literature contains reports of a number of smaller epidemics thus originating. Epidemics of typhoid fever have quite often been caused by an infected milk supply, and now and then diphtheria infection has been carried in this way. On the whole, however, such occurrences are not very frequent. There still remain to be considered the large number of cases and deaths from diarrheal disease in infants. How many of these can fairly be charged to a high bacterial content of the milk? Dr. Harrington thought a large percentage should be so charged, but Dr. Holt, who has given special attention to this phase of the subject, thought that by far the larger percentage should be charged to unhygienic surroundings, bad air, improper clothing, excessive hot weather, and the improper modification of cow's milk, for in this city most infants receive heated milk in summer, so that the diarrheas due to raw milk have already been largely eliminated. The extensive researches of Park and Holt showed that pasteurized polluted milk did not give as good results as pure raw milk, and that the latter gave about equally good results when raw as when pasteurized.

In discussing the question of pasteurization several of the speakers expressed entire disbelief in the efficacy of so-called "commercial pasteurization." This consists in passing the milk through heated coils, the temperature usually being about 160° F., and the time of passage varying from 15 to 30 seconds. It was claimed that pasteurization, in order to be of benefit, should kill all the tubercle bacilli that might possibly be present. This would require

a heating of at least twenty minutes to 145°, and anything short of this would be incomplete and useless. A critical examination of all the data, however, tends to show that this view is hardly tenable. As was well pointed out by Park, an exposure of thirty seconds to 160° F. does kill a large percentage of non-spore bearing bacteria. In a series of experiments now being carried on with a "commercial" pasteurizer at the health department laboratory, neither typhoid nor diphtheria bacilli withstood this degree of heat. Furthermore, certain European observers have found that even tubercle bacilli are injured by this heat, for infected milk thus heated usually did not infect guinea-pigs in feeding experiments, but only when injected. It has been claimed that pasteurized milk when kept for twenty-four hours usually shows a higher bacterial content than unheated milk, because of heated milk being a better soil for growth of bacteria. Park's experiments showed that ordinary milk really heated for thirty seconds to 160° F., and then kept in the ice-box for twenty-four hours, has less than ten per cent. of the number of bacteria which would have been present if the milk had been unheated and kept under the same conditions.

Following largely on the researches of Spolverini, there has been considerable discussion as to the importance and the functions of the ferments found in milk. Raudnitz, probably the foremost authority on the chemistry of milk, believes that the presence of the ferments is to be looked upon as in the nature of an excretion and of no particular significance. In the suppression of tuberculosis, as developed by von Behring, one of the main points is the production of a tuberculosis-immune milk for infant feeding. Such a milk cannot be pasteurized without at least partially destroying the protective substances So far as the digestibility of raw and pasteurized milk is concerned, there is also still considerable difference of opinion.

Repeating the recommendations we made in a previous issue, we believe it would be feasible for the health authorities to license a considerable percentage of farms to supply raw milk, provided all the cattle were subjected to the tuberculin test twice a year and to a physical examination by a competent veterinarian every three months. The animals that react to tuberculin and others found diseased would have to be removed. Furthermore, such farms should be held very strictly to requirements as to cleanliness, cooling of milk, freedom from contagion, etc., violation of which would be punishable by the exclusion of the milk from the city or by compulsory thorough pasteurization. Of course, a large staff of inspectors would be necessary to see that the farmers lived up to these requirements. So far as the milk supplied by farmers unwilling or unable to comply with such restrictions is concerned, we believe that pasteurization under the supervision of the health authorities should be insisted on. In order to insure efficient pasteurization a maximum bacterial content and a minimum heating should be established. Furthermore, every bottle of pasteurized milk should be plainly so marked, and the degree of heat, length of exposure, and date of treatment should also be stated.

ENDURANCE AND DIET.

THE claim is always made by vegetarians—the sober-minded among them as well as the fanatics—that the man who eschews flesh food is "fitter" than the meat-eater, but there has not been much evidence of this beyond the statements of the former regarding their subjective feelings. The carnivore has maintained that this was no proof, for the Eddyite made the same claim while eating anything in sight and despising every hygienic law. As a matter of fact, however, we may remark in parenthesis, the member of the Church of Christ Scientist, while pretending to ignore the laws of health, is a pretty fair hygienist, and takes very good care of her body, as a rule—especially if she aspires to the rôle and emoluments of a "reader." Vegetarians, too—at least the professionals—are not neglectful of hygienic laws in addition to the practice of their peculiar tenet. They avoid not only meat but also all the stimulating or exciting products of the vegetable kingdom, such as spices, coffee, and alcohol, and are given to an open-air life, deep breathing, and sensible clothing. The meat eaters with whom they contrast themselves are, moreover, usually the intemperate of their class, the heavy eaters and those who fill themselves to repletion with animal food three times a day. Nearly everyone admits that excessive consumption of meat is injurious, and a comparison of the strict vegetarian with the intemperate meat eater is manifestly unfair. It is as inconclusive as to compare the total abstainer from alcohol with the drunkard, rather than with the temperate wine drinker.

A comparative test of the respective powers of endurance of meat eaters and vegetarians, which eliminated some, though not all, of the unfairness of such comparisons, was recently made by Professor Irving Fisher of Yale University (*Yale Medical Journal*, March, 1907). The results obtained were interesting and worthy of consideration. The tests of endurance were three in number: holding the arms horizontally, deep knee bending, and leg raising. The subjects of the test were divided into three groups: athletes accustomed to a high-proteid and full-flesh dietary, athletes accustomed to a low-proteid and non-flesh dietary, and sedentary persons accustomed to a low-proteid and non-flesh dietary. The vegetarians had, with few exceptions, abstained from flesh food for periods varying from 4 to 20 years, and some had never eaten meat. The flesh eaters had, with few exceptions, been accustomed to take meat two or three times daily, so that they could not be called temperate meat eaters, and the test was therefore not quite fair from the point of view of the advocates of a moderate flesh dietary. The results were all in favor of the vegetarians, as shown by the following table:

	Arm Holding		Deep Knee Bending		Leg Raising	
	No. of Persons	Average Record Minutes	No. of Persons	Average Record Times	No. of Persons	Average Record Times
Flesh eaters, athletes	15	10	9	383	9	279
Abstainers, athletes	10	39	16	927	6	288
Abstainers, sedentary	13	64	5	535	1	74

A study of this table, though demonstrating the superior endurance of the vegetarians, brings out

some curious facts. In the matter of leg raising, excluding the one sedentary abstainer, the superiority of the abstaining athletes over the meat eaters of the same class was slight, but in knee bending it was more marked, even the sedentary abstainers beating the meat-eating athletes. In the arm-holding contest, not only did the abstainers far outstrip the meat eaters, but the sedentary abstainers were nearly twice as capable as the athletes of their own diet class. Manifestly one must look to something else than the diet to account for this greater muscular endurance on the part of those of sedentary pursuits.

Professor Fisher's experiments are interesting and the results are suggestive; though they are not conclusive as to the comparative merits of total abstinence from meat and of *moderate* indulgence. The tests would also have been more satisfactory had he included among his subjects a group of sedentary meat eaters. We have seen that the sedentary abstainers were superior to the athletic abstainers in the arm-holding test, and it would be interesting to know whether they would also be superior to meat eaters of their own class. That they would win in a contest with immoderate (three meals a day) meat eaters we think probable, but that either they or the abstaining athletes would prove better in the matter of endurance than open-air lovers, of temperate habits, who eat meat in moderation, has not been demonstrated. Comparison between extremists is of interest, but it is of little value to the average man. It simply indicates that total abstinence is better than overindulgence in what is a poison when taken in excess, but which the experience of mankind has demonstrated is a life-sustaining food when eaten in moderation.

The Desmoid Test Again.

During the past year or so the merits and demerits of Sahli's so-called desmoid test for determining the functional efficiency of the stomach have been discussed with considerable thoroughness by workers in the field of gastrointestinal diseases. Sahli has in so many ways shown himself a reliable guide that it would be unwise to arrive at an unfavorable conclusion in regard to this method unless those criticising it had a good deal of evidence on their side, but it must be conceded that as the case now stands it appears that the desmoid test is not destined to occupy the important position in clinical diagnosis that its originator hoped for. Lewinski, writing on the subject in the *Münchener medizinische Wochenschrift* of February 26, 1907, suggests that, as the conditions under which the desmoid test and the ordinary test meal are carried out are so different, some of the contradictions between the results obtained by the two methods may be explained in this way. He endeavored to make a fairer series of observations by resorting to Schmidt's test diet and comparing the result of the desmoid test with the amount of connective tissue from the meal found undigested in the stool. Out of thirty-two comparative tests made in this way on different patients, conflicting results were obtained in fifteen, or nearly one-half the number. Several suggestions are made by the author to account for this discrepancy, among others that different specimens of catgut, owing to the mode of manufacture of the raw material, may easily vary in their resistance to digestion, and the still more important observation that tests of various sorts *in vitro* showed that catgut may be digested in intestinal juice or in gastric juice apparently free from peptic ferment. While it will be a disappointment if the ingenious and simple method, proposed by Sahli as a substitute for the test meal with its many disagreeable features, turns out to be unsuitable for ordinary use, there is much in favor of Lewinski's recommendation that information of a similar nature be sought for by examining the stools after placing the patient on Schmidt's régime in order to ascertain the ability of the stomach to digest the connective tissue of the chopped meat forming part of this diet.

Industrial Diseases.

In a communication to the *Lancet* of March 9, 1907, in reference to the relation of industrial diseases to the Workmen's Compensation Act, Dr. A. J. Greene points out that unless this class of affections is very limited in number employers will be compelled, in order to protect themselves against damage suits, to have all their workmen medically examined before they are engaged, and declares that such a course would lead to the rejection of many who are now able to earn good wages. The economic outcome would be that the rejected ones would perforce become objects of charity, while those accepted would be able to demand higher wages, as their labor would be at a premium. Prices would go up and foreign competition would be increased. Official inquiries have been made with reference to chronic carbon monoxide poisoning, pulmonary fibrosis and chronic pneumonia, miner's nystagmus, miner's knee, and cardiac dilatation. The author shows that the symptoms of some of these conditions are extremely indefinite, and that it might be very difficult to determine whether a lowered vitality in a given case was due to any one of the foregoing causes or to some error of living or vicious habit with which the occupation itself had absolutely nothing to do. Many diseases to which the name of some occupation is attached are by no means confined to those who follow that particular calling.

The Presence of the Meningococcus in the Circulating Blood.

It is only within recent years that the meningococcus has been definitely demonstrated in the circulating blood and the possibility of a hematogenous origin in cerebrospinal meningitis acknowledged. The number of cases is, however, still limited so that every additional demonstration is of value. In a report made by Marcovich in the *Wiener klinische Wochenschrift*, No. 44, 1906, mention is made of a case in which the ordinary clinical features of epidemic cerebrospinal meningitis were absent and the presence of a peculiar skin eruption led to a diagnosis of typhus fever. There was no increase of temperature and no stiffness in the neck. The patient died within a few days after being taken sick, and the autopsy revealed the presence of a purulent meningitis along the convexity and the base of the brain. The ventricles were quite empty and the cerebrospinal fluid clear. The case is of particular bacteriological interest, because the blood obtained from a vein showed the meningococcus of Weichselbaum in pure culture. It is probable, therefore, that in this instance a meningococcus sepsis was the primary lesion and this was followed by a localization of the infectious process in the meninges.

Dangers Associated with the Starvation Cure.

In certain forms of gastric ulcer, a so-called starvation cure has been largely employed without much thought as to its general effects aside from those on the local process. Reichmann, however, writing in the *Archiv für Verdauungskrankheiten,* Vol. 11, No. 2, states as the result of an extended experience that the method of treatment known by this name may be the cause of numerous complications. In the first place we have to deal with the results of the diminished nutrition, weakness, vertigo, disturbances of the heart, etc., which may be developed to such an extent that the treatment must be stopped for a time at least if not altogether. The writer has also noted in a number of instances the production of a suppurative parotitis which he believes can be ascribed to the increased number of pyogenic bacteria which collect in the oral cavity and the duct of Steno as the result of an insufficient cleansing of the mucous membrane by the act of chewing and of a diminished flow of saliva. In order to protect the patient against these serious complications the oral cavity and particularly the mucous membrane of the cheeks should be kept as clean as possible with appropriate antiseptic solutions, among which Reichmann has found a four per cent. solution of boric acid among the most satisfactory.

Cancer Parasites.

Although the ranks of those who regard the cancer question from the standpoint of parasitology have been growing rather thinner of late, there seems to be no doubt in the minds of the believers in this doctrine that ultimately it will prevail. Schüller is one of the most assertive of the parasitologists, and in a recent number of the *Berliner klinische Wochenschrift* (March 4, 1907) he announces the forthcoming publication of a book in which he has explained the methods to be employed for the demonstration of his particular microorganism. He believes that the active proliferation of the cells in carcinoma and sarcoma depends on the local stimulation caused by the intracellular parasites, and gives in his article drawings reproduced from photographs, and intended to show the action of the invading organisms in inciting division of the nuclei. He closes by expressing the conviction that it may be regarded as absolutely certain that the development and growth of carcinoma and sarcoma in the human body are dependent on the parasites he has discovered.

News of the Week.

How the Earnings of the "Journal" Should be Expended.—In his presidential address before the Medical Society of the State of New York, in January of this year, Dr. Joseph D. Bryant, president-elect of the American Medical Association, referring to the prospective profits of the *Journal,* said: "I am, however, clearly of the opinion that the net earnings of the *Journal* should be utilized for its betterment, and for the purpose of extending, when feasible, publication courtesies to such of those as contribute to its pages important and original articles. It should not be the policy of this Society, in my judgment, to accumulate worldly belongings, but instead to increase the wealth of good fellowship and professional advance, by a wise adjustment relating thereto, of its business management."

Resolutions Regarding the Milk Supply.—The Section on Public Health of the New York Academy of Medicine passed the following resolution at its meeting of March 12, and this resolution was adopted by the Academy at its meeting on March 21:

Resolved: (1) That the Section on Public Health of the New York Academy of Medicine does not believe in the necessity of the compulsory pasteurization of all of the milk supply of New York City, but recommends for the present to all those whose milk supply cannot be proven to be thoroughly inspected and wholesome, and mainly the milk destined for the feeding of infants unless it is "certified," to boil their milk when delivered in the morning for three minutes. (2) That the health of the City of New York demands a persistence in the policy of supervision of farms, dairies, and creameries, supervision of the milk during transit and on delivery in the city, and supervision at the points of distribution in the city to the consumer, whether the milk that is distributed has been pasteurized or not. (3) That local and State health authorities and the Bureau of Animal Industry of the United States Department of Agriculture should cooperate with milk producers to prevent the occurrence of communicable disease in cattle and their caretakers. (4) That the Section on Public Health recommends that the New York Academy of Medicine adopt the above resolutions, and that a copy be sent to the members of the Committee on Public Health of the Board of Aldermen, to the Committee of the New York State Legislature having under consideration the Reece bill, and to the medical and the lay press.

Police to Aid in Suppression of Noise.—As the result of an appeal from Mrs. Isaac L. Rice, president of the Society for the Suppression of Unnecessary Noises, Police Commissioner Bingham has issued an order instructing every captain and commanding officer in the greater city to have all unnecessary noises stopped in the neighborhood of hospitals. The order calls attention to the fact that in the summer time, when it is necessary to keep hospital windows open, loud and boisterous talk on the adjacent streets disturbs the patients. Street vendors of all kinds, including lusty youths who yell "uxtry!" and sell late editions of the newspapers, are among the worst offenders. The small boy and the tin can make a combination that racks the nerves of sick people. Patrolmen are directed to insist that these unnecessary noises stop, particularly near hospitals, and, when necessary, to make arrests and explain to the Magistrates the necessity for so doing. Embodied in the order are sections of the Penal Code and the city ordinances relating to noises.

The Fight Against Tuberculosis in Chicago.—Efforts of the Chicago Tuberculosis Institute this year to reduce the death rate from this disease in Chicago will require $25,000, according to the estimates of its officials. Plans of the Institute include the establishment of a dispensary and a day camp, a comprehensive investigation of conditions in homes, workshops, stores, schools, public conveyances, traveling exhibits, and lectures and conferences. A successful camp sanatorium for women and girls in early stages of tuberculosis is being maintained at Dunning, Illinois. It is known as Camp Norwood. It cost only $2,000 to establish it, and it accommodates twenty patients.

Emergency Hospital, Chicago.—The Iroquois Memorial Emergency Hospital Association has

made an offer to construct an emergency hospital at a cost of not less than $25,000, near the loop downtown, provided a site can be had, and if the maintenance of the institution is undertaken.

Chicago Medical Colleges to be Inspected.—Arrangements were completed at a meeting of the State Board of Health, held March 15, for the inspection annually of the medical colleges of Chicago and Cook county. To find out whether or not all the provisions under which these colleges operate under the State law are being observed, these examinations are to be held by the Board.

The Biological Station of the University of California, at La Jolla, a suburb of San Diego, promises soon to become one of the most thoroughly equipped institutions of the kind. By recent enactments of the State legislature and the city council, a park has been set aside to the use of the station, and money has been contributed for putting up a suitable building. Work of a high order has been carried on for several years, and furnishes a basis for further undertakings. The station has been located at this point on account of the great variety of sea-life found in the vicinity.

Mosquito Extermination in New Jersey.—The Jersey City Board of Health has under consideration plans for exterminating mosquitos in the Hackensack meadows by a system of drainage ditches twenty miles in length. The main trenches emptying into the Hackensack river will be thirty inches deep, varying from two to four feet in width. The lateral ditches will be ten inches wide. The ditches will be dug by means of an excavating machine, and it is estimated that the cost of the work will not exceed $2,500.

Dr. Hermann Grad has been appointed assistant surgeon of the Woman's Hospital of this city.

Dr. Charles F. Millar, chief surgeon at the Central Emergency Hospital of San Francisco, has resigned from the service on account of ill-health. He has been connected with the health department for the past seven years, and displayed remarkable ability at all times, but especially in the trying times following the earthquake of a year ago.

Measles in the Navy.—An epidemic of measles has broken out on the battleship *Georgia*, now at Hampton Roads. A month ago about thirty of the seamen on the vessel suffered from the disease, and for a time it seemed that the epidemic had subsided, but new cases are occurring again, and orders for the future movements of the ship have been cancelled.

Alleged Attacks on Insane Patients.—Six former or present attendants of the State Hospital for the Insane in Cleveland have been indicted by the Grand Jury on the charge of having used undue violence toward patients in their care. One of these attendants has nine separate indictments against him.

To Prevent Seasickness.—The value of Dr. Schlick's gyroscopic apparatus, intended to reduce the motion of vessels at sea, has been attested by Sir William H. White, F.R.S., a British authority in maritime construction. At a meeting of the Institution of Naval Architects he said that from personal observation he could certify to the remarkable steadying effect on a vessel of the gyroscopic apparatus. In all cases its effect was to extinguish the rolling motion of the ship almost immediately. The vessel on which he had observed the working of the apparatus was practically deprived by it of rolling motion as she lay broadside to the sea. Sir William expressed the opinion that the apparatus would have great utility attached to Channel and coasting passenger steamers. Gyroscopes could also be designed which would have a steadying effect on the largest ocean liners.

Dr. C. E. Ruth, for many years Professor of Surgery in the Keokuk Medical College was guest of honor at a dinner given in Burlington, Ia., by his professional friends as a farewell on the occasion of Dr. Ruth's impending removal to Colorado.

McGill University Medical School.—The medical course at McGill University, Montreal, has been lengthened by a year, and five years of study are now requisite to obtain the degree of M.D. from that faculty.

Standardized Sausage.—The *Lancet*, which has already made suggestions in regard to the standardization of Christmas puddings and the height of the steps in staircases, now advocates the adoption of a "legal authoritative definition of a sausage." It is admitted that sausages, as a whole, are nowadays usually composed of wholesome ingredients, though this useful comestible is a common subject of jest, since it is so often regarded as a convenient vehicle for materials which when undisguised certainly do not appeal to us as being suitable or even wholesome for purposes of food. One particular abuse to which the *Lancet* objects is the addition of bread or broken waste biscuit with the object of cheapening the product. This is a palpable fraud, as the sausage is looked upon as a meaty and not a farinaceous food, and, moreover, the price is approximately that of meat.

Prof. Behring Recovered.—Cable despatches announce that von Behring, who was lately said to have been suffering from a mental breakdown, has entirely recovered again and will not be obliged to give up work for the present.

Paris Morgue Closed to Visitors.—The municipal authorities have decided that the Paris morgue is no longer to be open to sightseers, and that in future no persons shall be admitted to inspect the bodies unless they can convince the registrar that they come for the purpose of identifying a corpse.

Absinthe to be Tabooed in France.—The commission on hygiene of the French Chamber of Deputies has reported in favor of the total prohibition of the distillation, importation, traffic in, and sale of absinthe. The commission proposes that the manufacture of absinthe shall cease in one year, and that after two years its sale shall become illegal.

Smallpox.—The sporadic occurrence of a few cases of smallpox in Paris and various other French cities is said to have caused much popular apprehension in Paris, and great numbers of people of all classes are being vaccinated. The Parisian cases are supposed to have been imported from Tunis and Tripoli, and were of a severe type. The transatlantic liner *Pennsylvania* was detained at Quarantine last week owing to the presence on board of a case of the disease. The patient, a child, was removed to the Brooklyn Hospital and the steamer was fumigated. Those of the passengers who had been more directly exposed were sent to Hoffman Island for observation.

Prof. Karl Hess of Würzburg, a prominent ophthalmologist, sails for this country on April 9 to give lectures on subjects relating to his specialty in various cities.

Hospital Appropriations.—The Legislature of California recently made the following appropriations: For improvements at the Southern California State Hospital, $45,000; for improvements at the Home for the Care of Feeble-minded Children, $100,000; for the State Hospital at Napa, $63,000; for additional building at the Stockton State Hospital, $78,000.

Bequests to Public Institutions.—By the will of the late Francis P. Furnald, Columbia University will inherit $300,000 on the death of the wife of the testator, Mrs. Sarah E. Furnald, to whom all his estate is left in trust for her life. The trustees of the Presbyterian Hospital will receive on Mrs. Furnald's death $100,000, to be spent in maintaining beds for worthy applicants, and the Bethany Day Nursery and the Manhattan Working Girls' Society will also receive $100,000 each to create funds in memory of Mrs. Furnald.

Bequests to Hospitals.—By the will of the late Samuel Elkin of Philadelphia the sum of $5,000 is bequeathed to the Jewish Hospital in the name of his mother, Eve Elkin; $3,000 to the Jewish Foster Home, also in the name of his mother; $3,000 to the operating department of Jefferson Hospital; $5,000 to the Episcopal Hospital; $5,000 to the Presbyterian Hospital; $5,000 to St. Agnes' Hospital, and $10,000 to the Home for Crippled Children.

Sanatorium Gabriels.—Those in charge of this institution, which is intended for the care of patients in the earlier stage of tuberculosis, state that it is handicapped seriously by lack of funds. The sanatorium is situated at Paul Smith's in the Adirondacks, and was begun in 1895. The sum of $135,000 has been spent on buildings and equipment and $50,000 has been expended on interest. The debt is now $65,000, of which $18,461 must be met before May 24.

Roane County (Tenn.) Medical Association.—At the last meeting of this society, officers for the ensuing year were elected as follows: *President,* Dr. J. J. Waller of Oliver Springs; *Vice-President,* Dr. John Roberts of Kingston; *Secretary,* Dr. G. C. G. Givan of Harriman, reelected; *Treasurer,* Dr. C. W. Green of Harriman, reelected.

Western Massachusetts Homeopathic Association.—At the annual meeting of this society held in Springfield on March 21, officers were elected as follows for the ensuing year: *President,* Dr. H. C. Cheney of Palmer; *First Vice-President,* Dr. E. W. Capen of Monson; *Second Vice-President,* Dr. S. A. Lewis of Springfield; *Secretary and Treasurer,* Dr. James B. Comins of Springfield.
